

An aerial photograph of a savanna landscape. The ground is covered in dense green grass with a network of dark, winding paths or water channels. A herd of elephants is scattered across the lower half of the image, some standing and some partially submerged in the paths. Several white birds are also visible, some standing on the grass and others in flight.

To all who are curious about life and how it works

# ABOUT THE AUTHORS

**JAMES R. MORRIS** is Professor of Biology and Chair of the Program in Health: Science, Society, and Policy at Brandeis University. He teaches a wide variety of courses for majors and non-majors, including introductory biology, evolution, genetics and genomics, epigenetics, comparative vertebrate anatomy, and a first-year seminar on Darwin's *On the Origin of Species*. He is the recipient of numerous teaching awards from Brandeis and Harvard. His research focuses on the rapidly growing field of epigenetics, making use of the fruit fly *Drosophila melanogaster* as a model organism. He currently pursues this research with undergraduates in order to give them the opportunity to do genuine, laboratory-based research early in their scientific careers. Dr. Morris received a PhD in genetics from Harvard University and an MD from Harvard Medical School. He was a Junior Fellow in the Society of Fellows at Harvard University, and a National Academies Education Fellow and Mentor in the Life Sciences. He also writes short essays on science, medicine, and teaching at his Science Whys blog (<http://blogs.brandeis.edu/sciencewhys>).

**DANIEL L. HARTL** is Higgins Professor of Biology in the Department of Organismic and Evolutionary Biology at Harvard University and Professor of Immunology and Infectious Diseases at the Harvard T. H. Chan School of Public Health. He has taught highly popular courses in genetics and evolution at both the introductory and advanced levels. His lab studies molecular evolutionary genetics and population genetics and genomics. Dr. Hartl is the recipient of the Samuel Weiner Outstanding Scholar Award as well as the Gold Medal

of the Stazione Zoologica Anton Dohrn, Naples. He is a member of the National Academy of Sciences and the American Academy of Arts and Sciences. He has served as President of the Genetics Society of America and President of the Society for Molecular Biology and Evolution. Dr. Hartl's PhD is from the University of Wisconsin, and he did postdoctoral studies at the University of California, Berkeley. Before joining the Harvard faculty, he served on the faculties of the University of Minnesota, Purdue University, and Washington University Medical School. In addition to publishing more than 400 scientific articles, Dr. Hartl has authored or coauthored 30 books.

**ANDREW H. KNOLL** is Fisher Professor of Natural History in the Department of Organismic and Evolutionary Biology at Harvard University. He is also Professor of Earth and Planetary Sciences. Dr. Knoll teaches introductory courses in both departments. His research focuses on the early evolution of life, Precambrian environmental history, and the interconnections between the two. He has also worked extensively on the early evolution of animals, mass extinction, and plant evolution. He currently serves on the science team for NASA's mission to Mars. Dr. Knoll received the Phi Beta Kappa Book Award in Science for *Life on a Young Planet*. In 2018, he was awarded the International Prize for Biology. He is a member of the National Academy of Sciences and a foreign member of the Royal Society of London. He received his PhD from Harvard University and then taught at Oberlin College before returning to Harvard.

**ROBERT A. LUE** is Professor of Molecular and Cellular Biology at Harvard University and the Richard L. Menschel Faculty Director of

the Derek Bok Center for Teaching and Learning. Dr. Lue has a longstanding commitment to interdisciplinary teaching and research and chaired the faculty committee that developed the first integrated science foundation in the country to serve science majors as well as pre-medical students. The founding director of Life Sciences Education at Harvard, Dr. Lue led a complete redesign of the introductory curriculum, redefining how the university can more effectively foster new generations of scientists as well as science-literate citizens. Dr. Lue has also developed award-winning multimedia, including the animation “The Inner Life of the Cell.” He has coauthored undergraduate biology textbooks and chaired education conferences on college biology for the National Academies and the National Science Foundation and on diversity in science for the Howard Hughes Medical Institute and the National Institutes of Health. In 2012, Dr. Lue’s extensive work on using technology to enhance learning took a new direction when he became faculty director of university-wide online education initiative HarvardX; he now helps to shape Harvard’s engagement in online learning to reinforce its commitment to teaching excellence. Dr. Lue earned his PhD from Harvard University.

**MELISSA MICHAEL** is Director for Core Curriculum and Assistant Director for Undergraduate Instruction for the School of Molecular and Cellular Biology at the University of Illinois at Urbana-Champaign. A cell biologist, Dr. Michael primarily focuses on the continuing development of the School’s undergraduate curricula. She is engaged in several projects aimed at improving instruction and assessment at the course and program levels. Her research focuses primarily on how creative assessment strategies affect student learning outcomes and

how outcomes in large-enrollment courses can be improved through the use of formative assessment in active classrooms.

**ANDREW BERRY** is Lecturer in the Department of Organismic and Evolutionary Biology and an undergraduate advisor in the Life Sciences at Harvard University. With research interests in evolutionary biology and history of science, he teaches courses that either focus on one of the areas or combine the two. He has written two books: *Infinite Tropics*, a collection of the writings of Alfred Russel Wallace, and, with James D. Watson, *DNA: The Secret of Life*, which is part history, part exploration of the controversies surrounding DNA-based technologies.

**ANDREW A. BIEWENER** is Charles P. Lyman Professor of Biology in the Department of Organismic and Evolutionary Biology at Harvard University and Director of the Concord Field Station. He teaches both introductory and advanced courses in anatomy, physiology, and biomechanics. His research focuses on the comparative biomechanics and neuromuscular control of mammalian and avian locomotion, with relevance to biorobotics. He is currently Deputy Editor-in-Chief for the *Journal of Experimental Biology*. He also served as President of the American Society of Biomechanics.

**BRIAN D. FARRELL** is Director of the David Rockefeller Center for Latin American Studies and Professor of Organismic and Evolutionary Biology and Curator in Entomology at the Museum of Comparative Zoology at Harvard University. He is an authority on coevolution between insects and plants and a specialist on the biology of beetles.

He is the author of many scientific papers and book chapters on the evolution of ecological interactions between plants, beetles, and other insects in the tropics and temperate zone. Dr. Farrell also spearheads initiatives to repatriate digital information from scientific specimens of insects in museums to their tropical countries of origin. In 2011–2012, he was a Fulbright Scholar to the Universidad Autónoma de Santo Domingo in the Dominican Republic. Dr. Farrell received a BA in Zoology and Botany from the University of Vermont and MS and PhD from the University of Maryland.

**N. MICHELE HOLBROOK** is Charles Bullard Professor of Forestry in the Department of Organismic and Evolutionary Biology at Harvard University. She teaches an introductory course on plant biology as well as advanced courses in plant physiology. Her research focuses on the physics and physiology of vascular transport in plants with the goal of understanding how constraints on the movement of water and solutes between soil and leaves influences ecological and evolutionary processes. Dr. Holbrook received her PhD from Stanford University.

## ASSESSMENT AUTHORS

**JEAN HEITZ** is a Distinguished Faculty Associate at the University of Wisconsin in Madison, WI. She has worked with the two-semester introductory sequence for biological sciences majors for over 40 years. Her primary roles include developing both interactive discussion/recitation activities designed to uncover and modify misconceptions in biology and open-ended investigative labs designed to give students a more authentic experience with science. The lab experience includes engaging all second-semester students in

independent research, either mentored research or a library-based meta-analysis of an open question in the literature. She is also the advisor to the Peer Learning Association and is actively involved in TA training. She has taught a graduate course in Teaching College Biology, has presented active-learning workshops at a number of national and international meetings, and has published a variety of lab modules, workbooks, and articles related to biology education.

**MARK HENS** is Associate Professor of Biology at the University of North Carolina Greensboro, where he has taught introductory biology since 1996. He is a National Academies Education Mentor in the Life Sciences and is the director of his department's Introductory Biology Program. In this role, he guided the development of a comprehensive set of assessable student learning outcomes for the two-semester introductory biology course required of all science majors at UNCG. In various leadership roles in general education, both on his campus and statewide, he was instrumental in crafting a common set of assessable student learning outcomes for all natural science courses for which students receive general education credit on the 16 campuses of the University of North Carolina system.

**ELENA R. LOZOVSKY** is Principal Staff Scientist in the Department of Organismic and Evolutionary Biology at Harvard University. She received her PhD in genetics from Moscow State University in Russia and before joining Harvard carried out research at the Institute of Molecular Biology in Moscow, Cornell University, and Washington University School of Medicine in St. Louis. Her research has focused on transposable elements and genome evolution in

eukaryotes and on the evolution of drug resistance in malaria parasites. She has also had extensive experience in teaching genetics and evolution.

**JOHN MERRILL** is Director of the Biological Sciences Program in the College of Natural Science at Michigan State University. This program administers the core biology course sequence required for all science majors. He is a National Academies Education Mentor in the Life Sciences. In recent years he has focused his research on teaching and learning with emphasis on classroom interventions and enhanced assessment. A particularly active area is the NSF-funded development of computer tools for automatic scoring of students' open-ended responses to conceptual assessment questions, with the goal of making it feasible to use open-response questions in large-enrollment classes.

**RANDALL PHILLIS** is Associate Professor of Biology at the University of Massachusetts Amherst. He has taught in the majors introductory biology course at this institution for 19 years and is a National Academies Education Mentor in the Life Sciences. With help from the Pew Center for Academic Transformation (1999), he has been instrumental in transforming the introductory biology course to an active learning format that makes use of classroom communication systems. He also participates in an NSF-funded project to design model-based reasoning assessment tools for use in class and on exams. These tools are being designed to develop and evaluate student scientific reasoning skills, with a focus on topics in introductory biology.

**DEBRA PIRES** is an Academic Administrator at the University of California, Los Angeles. She teaches the introductory courses in the Life Sciences Core Curriculum. She is also the Instructional Consultant for the Center for Education Innovation & Learning in the Sciences (CEILS). Many of her efforts are focused on curricular redesign of introductory biology courses. Through her work with CEILS, she coordinates faculty development workshops across several departments to facilitate pedagogical changes associated with curricular developments. Her current research focuses on what impact the experience of active learning pedagogies in lower-division courses have on student performance and concept retention in upper-division courses.

# BIOLOGY: HOW LIFE WORKS

has been a revolutionary force for both instructors and students in the majors biology course. It was the first truly comprehensive set of integrated tools for introductory biology, seamlessly incorporating powerful text, media, and assessment to create the best pedagogical experience for students.

**THE VISUAL PROGRAM** The already impressive visual program has been greatly improved and expanded. The powerful **Visual Synthesis tools** have been reimagined, allowing for more flexibility for both students and instructors. A new **Tour Mode** allows for learning objective–driven tours of the material. We’ve also added deep-linking from the eText to encourage the student to jump immediately from the reading experience into a more interactive visual representation of the content. Instructors can also create customized tours to use for engaging in-class presentation and active learning opportunities. And finally, new animations have been added to the library, including a new 3D animation to support the animal form and function chapters.

**A FOCUS ON SCIENTIFIC SKILLS** The third edition has an increased focus on helping students develop the skills they will need to be successful scientists. We’ve designed skills learning experiences not separate from the core content, but aligned to it. New **Skills Primers** are self-paced tutorials that guide students to learn, practice, and use skills like data visualization, experimental design, working with numbers, and more. New **How Do We Know Activities** are digital extensions of the application-based learning tool found in the text, and focus on further developing students’ scientific inquiry skills.

**THE HUB** The best teaching resources in the world aren't of use if instructors can't find them. The **HUB** provides a one-stop destination for valuable teaching and learning resources, including all of our well-vetted in-class activities.

**IMPROVED ORGANIZATION OF TOPICS** We implemented several organizational changes based on extensive user feedback with the goal of creating an improved narrative for students and a more flexible teaching framework for instructors.

A new chapter on **Animal Form, Function, and Evolutionary History** leads off the animal anatomy and physiology chapters to provide a whole-body view of structure and function and to provide better context for the more specific systems in following chapters.

The ecology coverage has been enriched and reorganized for a more seamless flow. A new chapter on **Ecosystem Ecology** combines ecosystem concepts formerly housed in separate chapters to present a more cohesive view of the flow of matter and energy in ecosystems.

All of these changes and improvements represent the next step in the evolution of *Biology: How Life Works*. We think we have created the best learning resource for introductory biology students, and we think instructors will find joy in the improvements they can make in their classes with these materials.

**DEAR STUDENTS AND INSTRUCTORS,**

A new edition of *How Life Works* provides an opportunity for us to continue to innovate. It gives us a chance not just to update and

organize, but also to rethink and reimagine the resources we develop to support teaching and learning in introductory biology. Many of our revisions are based on what we've heard from you—the growing community of students and instructors who use *How Life Works*.

From the start, we have written *How Life Works* to be a streamlined text that focuses on concepts and skills relevant to introductory biology. We take an integrated approach that aims to connect concepts and processes, so students can see their interrelationships. Instead of presenting vast amounts of content, we organize our presentation around a few key core concepts. And we recognize that the text, media, and assessment have to work together to provide a rich and meaningful learning experience for students. Our digital platform is designed to provide maximum flexibility and ease of use. With each edition, we keep these ideas front and center.

The third edition continues and expands on this approach. We are particularly excited about new resources that help to develop skills that students will encounter in introductory biology and beyond, including how to ask questions, develop hypotheses, interpret data, read graphs, use quantitative reasoning, and apply statistical and evolutionary thinking. In short, our new resources emphasize the skills that enable students to think like scientists.

Every chapter includes at least one **How Do We Know Figure**, which takes the time to describe how the scientific community came to know a piece of information, process, or concept presented in the text. These were so well received in the first and second editions that we decided

to connect them to **How Do We Know Activities** that ask students to answer questions and explore the figure actively and in depth.

In addition, we have revised and expanded the **Primers** that we developed in earlier editions so that they focus on skills and include media and assessment. In this way, they are interactive and serve as short tutorials on fundamental skills.

We also took a fresh look at the chapters on animal anatomy and physiology. A new case focuses on the exciting field of biology-inspired design. This interdisciplinary field taps into biology, engineering, and material science to build tools and devices inspired by all types of organisms, including animals. In addition, a new chapter on animal form, function, and evolution provides a way to orient students to main concepts before delving into detail in the subsequent chapters. Finally, we have new media and assessment that work closely with this section.

In response to thoughtful feedback from instructors, we reorganized our coverage of ecological systems. We now bring together in a single chapter an integrated discussion of flow of matter and energy in ecosystems. This new arrangement allows us to move seamlessly from organisms to populations to species interactions to interactions with the physical environment to global ecology, ending with a discussion of the impact of human activities on the biosphere.

The pace of change in biology is matched by our ever-growing understanding of how students learn, drawing on the latest findings in neuroscience, psychology, and education. We think about ways to

create a classroom that is active, inclusive, and evidence-based. We ask ourselves questions as we work to make our material more student-focused. Can we replace a short lecture with an activity in which students construct their own knowledge? What are some common misconceptions that students might encounter along the way? Do all students feel supported and encouraged?

Toward this end, in our new edition we have added a **Learning Objective Framework** while continuing to diversify our assessments. We focus on high-order questions and visual interpretation questions that ask students to make sense of a graph or figure. We continue to expand our rich collection of in-class activities to provide support for instructors who are leading student-centered classrooms. **Assessments** are found everywhere in *How Life Works*—associated with the text, figures, animations, simulations, maps, and in-class activities.

Finally, our media program continues to be fresh and creative, while staying aligned with our other resources. In this edition, we have redesigned our **Visual Synthesis Maps** to provide new functionality. Students can still freely explore spaces and processes in these maps, but we now offer “tours” based on learning objectives so that students can follow a path as a way to focus their exploration.

As one of our recent adopters said, hearteningly, “**Who is the book for?**” **if not for students.** That simple question guides everything we do. With every edition and update, we aim to improve the learning experience as students engage in discovering how life works.

Sincerely,

The *How Life Works* team

# CONNECTED VISUAL TOOLS

The art in the text of *Biology: How Life Works* and the associated media in LaunchPad were developed in coordination with the text and assessments to present an integrated and engaging visual experience for students.

Two of the biggest challenges introductory biology students face are connecting concepts across chapters, and building a contextual picture, or visual framework, of a complex process. To help students think like biologists, we provide **Visual Synthesis Figures** at key points in the text with associated **Visual Synthesis Maps** in the media package. These figures bring together multiple images students have already seen into a visual summary, helping students see how individual concepts connect to tell a single story.

## REIMAGINED VISUAL SYNTHESIS PROGRAM

The **Visual Synthesis Tool's** user experience has been reimagined to provide students a more effective visual learning environment, helping them synthesize the connections between biological concepts.

**New Tour Mode Functionality:** As in previous editions of *How Life Works*, students will still have the opportunity to freely explore these visual concept maps. However, we have now rebuilt the visual synthesis tool to provide students with learning objective–driven tours of the major concepts being visualized in the map. Through these synthesis-focused tours, students follow defined pathways through the core concepts of the maps, as well as measure their understanding of the tours through aligned and assignable assessment opportunities. Instructors will also be able to create their own tours for students to explore in assignments, or for use as in-class teaching resources.

**Deep-link from the eText to the Visual Synthesis Map:** Students, with one click of a button, will be taken from their digital reading experience into the exact spot in our **Visual Synthesis Maps** where a particular figure/visualization from the book appears. These deep links will provide students with additional information about the figure, an enhanced visual opportunity to learn the concept, and the unique experience of seeing how this figure connects into the larger conceptual framework of the map.

## REIMAGINED 3D ANIMATIONS

The powerful **3D Animations** have been reimagined as more flexible tools for students. While still available as full-length videos, they are also available split into shorter clips of more manageable length with added annotations and an improved alignment of the assessments. New animations have been added to the library, including a new 3D animation to support the revised animal form and function topics.

# CONNECTING SKILLS

*How Life Works* is dedicated to teaching the skills students need to think critically, along with the concepts and content they'll need for success in later biology courses.

## SKILLS PRIMERS

1. Quantitative Reasoning: Working with Numbers
2. Scientific Inquiry: Asking and Answering Questions in Biology
3. Data and Data Visualization: Interpreting and Presenting Results
4. Phylogenetics: Reading and Building Evolutionary Trees
5. Probability and Statistics: Predicting and Analyzing Data
6. Models: Visualizing Biological Structures and Processes

**Skills Primers** are a new approach to developing the scientific, biological, and cognitive skills students need to be successful in an introductory biology course. The Skills Primers are tutorial-based resources that guide students to learn, practice, and use skills like data visualization, experimental design, working with numbers, and many more.

**How Do We Know Activities** ask students questions connected to How Do We Know Figures in the text. In answering these questions, students explore the figures in depth and develop the skills they need to understand scientific inquiry. These online companion exercises are assignable and gradable.

## HOW DO WE KNOW?

FIG. 33.18

### Do animals tend to get bigger over time?

**BACKGROUND** Cope's rule, named after the American paleontologist Edward Cope, suggests that there is a trend through time toward increasing size among animals. However, it is unclear whether such a general trend actually exists. Large body size can be associated with increased fitness—for example, by making it easier to capture prey or compete with other organisms. Notable examples of very large animals that lived long ago are the dinosaurs. There are also exceptions to this trend in some groups of animals.

**HYPOTHESIS** Animals tend to increase in size over evolutionary time.

**EXPERIMENT** Jonathon Payne and his colleagues at Stanford University decided to test the hypothesis that animals tend to get bigger over time, focusing on marine animals over the last 541 million years. They measured the three major body axes of images of animal specimens to determine the mean volume (as a measure of body size) for more than 17,000 genera of animals, including arthropods, brachiopods, echinoderms, mollusks, and chordates.

**RESULTS** The researchers found that the mean volume for all genera increased over time (the dark black line in the graph). In addition, they found that the range in sizes increased dramatically (the difference between the two light black lines in the graph). Most of this expansion resulted from an increase in the maximum size of animals (the upper light black line in the graph).

**CONCLUSION** The data support the hypothesis that there is an evolutionary trend toward larger body size in many groups of animals.

**FOLLOW-UP WORK** The researchers next asked whether the increase in size is the result of natural selection or genetic drift (Chapter 20). They compiled observed trends in the mean, maximum, and minimum sizes of a number of animal groups and compared them to the predictions of models based on selection and drift. They found that their observations are consistent with models based on selection, and not consistent with models based on drift. These findings suggest that increased body size has selective advantages.

# CONNECTED LEARNING TOOLS

**the HUB For Active Learning**

**Biology: HOW LIFE WORKS**

A collection of over 40 in-class activities, designed with real instructors in mind. Each activity comes with a detailed guide that introduces the activity, outlines learning objectives, and provides guidance on how to easily implement the activity in your class.

**Learning Objectives**  
After completing this activity, students should be able to:

- Trace the important transfers and transformations of matter and energy that take place during the major stages of cellular respiration and fermentation.

**List of Materials**

| Activity name                       | Preview                 | Download                          |
|-------------------------------------|-------------------------|-----------------------------------|
| Activity Guide                      | <a href="#">Preview</a> | <a href="#">Download</a> PDF, DOC |
| In-Class Presentation for Version 2 | <a href="#">Preview</a> | <a href="#">Download</a> PDF, PPT |
| In-Class Presentation for Version 2 | <a href="#">Preview</a> | <a href="#">Download</a> PDF, PPT |
| Student Handout for Version 2       | <a href="#">Preview</a> | <a href="#">Download</a> PDF      |

**Chapter 1: Making Life Work: Capturing and Using Energy**  
Activities: 1. Biomolecular

**Chapter 2: Cellular Respiration: Harvesting Energy from Carbohydrates and Other Fuel Molecules**  
Activities: 1. Metabolic Transformation, 2. Respiration Beyond Biology

**Chapter 3: Photosynthesis: Using Sunlight to Build Carbohydrates**  
Activities: 1. Photosynthesis: Biochemical Pathways

**Cellular Respiration and Photosynthesis Diagram**

Morris, *Biology: How Life Works, 3e*, © 2019 W. H. Freeman and Company

*How Life Works* has always been committed to providing powerful and effective resources for instructors and pedagogical support for students. The third edition expands this support with even better tools for self-study ahead of class and active work in the classroom.

**The Hub** is the teaching and learning destination of *How Life Works*. The Hub provides an easy way to find teaching and learning resources, including all of our in-class activities.

**Chapter Reading Guides:** Designed to improve and focus the reading experience, the reading guides provide students with easy access to chapter resources, including the **Learning Objective Framework** and answers to the **Self-Assessment Questions**.

**In-Class Activities:** Active learning exercises provide students with hands-on exploration and help correct common misconceptions. In-class activities contain all of the resources to engage students in an active classroom, including a preparation guide for instructors, in-class presentation slides with assessment questions, and student handouts. The third edition of *How Life Works* includes 10 new in-class activities for the second half of the text.

# CONNECTED ASSESSMENT

Well-designed assessment is a tremendous tool for instructors preparing students for class, engaging students during class, and gauging student understanding. The *How Life Works* assessment author team applied decades of experience researching and implementing assessment practices to create a variety of questions and activities for pre-class, in-class, homework, and exam settings. All assessment items are carefully aligned with the text and media and have the flexibility to meet the needs of instructors with any experience level, classroom size, or teaching style.

**Objectives:** We've authored a two-tier learning objective structure wherein **Level 1 objectives** are broader and more cognitively complex while our **Level 2 objectives** are more granular and typically less complex. Together these objectives describe what the learner should know and be able to do by the end of the learning experience. LaunchPad makes it easy to select assessments associated with these objectives, and to focus on the learning objectives that are most important to your course.

**Improved Assessments:** We have developed more high-order questions, more questions that support the development of quantitative skills, and more questions that require students to engage with figures or consider graphically represented data. Improved data analytics provide insight into student performance.

Toucans are frugivorous (fruit-eating) birds that inhabit tropical forests in Central and South America where they can potentially consume any fruit that is available (generalists). The realized niches of toucans are determined by competition in the consumption of different species of fruits (niche overlap). White-throated toucans are the largest species and very strong competitors who easily scare the mid-sized Cuvier's and Ivory-billed toucans off the fruiting trees, altering access to the resources among the three species. The graphs shown represent the occupation of niche space at two different sites, where two or three species coexist, in different abundances.

Which of the graphs shown best characterizes the fundamental niche of any of these species of toucans? Assume the X-axis is the niche space available.

# CONNECTING THROUGH LAUNCHPAD

Ordinarily, textbooks are developed by first writing chapters, then making decisions about art and images, and finally assembling a test bank and ancillary media. The authors of *How Life Works* developed the text, visual program, and assessment at the same time. These three threads are tied to the same set of core concepts, share a common language, and use the same visual palette, which ensures a seamless learning experience for students throughout the course.

The text, visuals, and assessments come together most effectively through **LaunchPad, Macmillan's integrated learning management system**. In LaunchPad, students and instructors can access all components of *How Life Works*.

LaunchPad resources for *How Life Works* are flexible and aligned. Instructors have the ability to select the visuals, assessments, and activities that best suit their classroom and students. All resources are aligned to one another as well as to the text to ensure effectiveness in helping students build skills and develop knowledge necessary for a foundation in biology.

**LearningCurve's game-like quizzing** motivates each student to engage with the content, and reporting tools help teachers get a handle on their class needs.

# WHAT'S NEW IN THE THIRD EDITION?

## MAJOR CHANGES AND UPDATES TO THE BOOK

In developing the third edition of *Biology: How Life Works*, we focused particularly on the form and function chapters and the ecology chapters.

**New introductions set the scene for the plant and animal form and function chapters and highlight key themes in structure/function relationships.**

- A new chapter, “Animal Form, Function, and Evolutionary History” ([Chapter 33](#)), leads off the animal physiology chapters. This chapter provides a whole-body view of structure and function that provides context for the specific systems discussed in the chapters that follow. It focuses on animal body plans and tissue types and introduces homeostasis as the major regulatory theme of the animal physiology chapters.
- The first section of “Plant Form, Function, and Evolutionary History” ([Chapter 27](#)) is a completely reconceived introduction to the plant form and function chapters. This section highlights major structure/function differences distinguishing bryophytes and vascular plants. It focuses on how the two groups maintain hydration, specifically on how the reliance on diffusion by bryophytes and bulk flow by vascular plants is reflected in overall structure and cell properties.

**Structure/function relationships are placed in a broader evolutionary framework.**

- The new “Animal Form, Function, and Evolutionary History” chapter ([Chapter 33](#)) concludes with an overview of the history of animal evolution, placing major anatomical and physiological innovations in an evolutionary context.
- “Plant Diversity” ([Chapter 31](#)) is now organized around four major structure/function transitions in the evolution of plant life, highlighted in a new [Section 31.1](#).

**The relationship between structure and function has been further strengthened in the plant chapters.**

We have recrafted several discussions of vascular structure and root structure to further clarify these structures and their effect on the resilience and efficiency of plant systems. In particular, the third edition provides a more thorough and insightful understanding of the mechanism of xylem transport.

**The animal physiology chapters begin with a new introductory case that highlights structure/function relationships.**

A new and engaging case on Biology-Inspired Design explores how scientists have mimicked nature to solve all kinds of practical problems of real-life interest to students, from Velcro to dialysis machines. Most animal physiology chapters contain a section discussing an example of biology-inspired design.

**Ecology coverage has been enriched and reorganized for a more seamless flow.**

A new chapter on Ecosystem Ecology, [Chapter 46](#), combines ecosystem concepts such as food webs and trophic pyramids with the material on biogeochemical cycles formerly in separate chapters to present a more cohesive view of the flow of matter and energy in ecosystems. This new arrangement allows us to move seamlessly from organisms to populations to species interactions to interactions with the physical environment to global ecology, ending with a discussion of the impact of human activities on the biosphere.

We continue to expand our treatment of ecological systems, one of our six grand themes. Chapters 44 and 45 (“Population Ecology” and “Species Interactions and Communities”) have been enriched by the addition of new concepts and examples to deepen the discussions of life histories and tradeoffs, island biogeography, the niche, biodiversity, and succession, among other topics.

## NEW CASE ON BIOLOGY- INSPIRED DESIGN

FIG. 33.2 Symmetry in animal form. (a) Radial versus bilateral symmetry.

a. Radial symmetry

The jellyfish displays radial symmetry: it has a body axis that runs from mouth to base, but many planes of symmetry around the axis.

the eyespots of flatworms are located at one end of the body, as are the brain and sense organs of earthworms, insects, and vertebrates (Fig. 33.3). The concentration of nervous components at one end of the body, defined as the

the internal organs against hard blows to the body and enables the body to turn without twisting these organs. Once molecular studies were conducted, however, researchers discovered that they did not support this traditional phylogenetic division of bilaterians into acoelomate, coelomate, and pseudocoelomate groups. Similarly, molecular sequence comparisons have not supported the once widespread view that segmented bodies indicate a close relationship between earthworms and lobsters.

### CASE 7 BIOLOGY-INSPIRED DESIGN: USING NATURE TO SOLVE PROBLEMS

#### Can we mimic the form and function of animals to build robots?

Scientists who design robots often try to mimic the form and function of animals. Fishes are one of the most popular types of robotic animals. We can learn a great deal about innovations by studying fishes, whose remarkable adaptations have been shaped by natural selection over more than 500 million years.

The first robotic fish was created in the 1980s by a team of scientists and engineers at Massachusetts Institute of Technology. It was called RoboTuna because it mimicked the form and function of a tuna, allowing it to swim effectively through water. Since then, many more fish-like robots have been made, so that today there are more than 400 different types of robotic fishes. Some, like RoboTuna, have one joint; others have many joints; and still others are made of dynamic materials that can bend fluidly.

Why build a robotic fish? The first and most basic reason is to understand how fish move. Fish are spectacular swimmers. If we can build a robotic fish that swims like a living one, it suggests that we understand how a fish is able to move forward, turn, and navigate its surroundings. Robotic fishes can also be used in studies of fish behavior. A robotic fish that looks and even smells like a real fish, and that has sensors to detect and record its surroundings, provides a way to quietly "spy" on fish in a way that is not possible by direct observation or by the use of cameras. There are all kinds of practical applications of robotic fish as well, from mapping coastlines, coral reefs, and the sea floor, to monitoring underwater cables and pipelines, to exploring marine life.

Scientists and engineers have copied the form and function of many animals, including cockroaches, geckos, jellyfish, hummingbirds, and bats, to name just a few. One of the most recent and exciting robots is based on an octopus. Octopuses show incredible dexterity and strength, all without an internal skeleton.

The robot octopus, called an octobot and designed by researchers at Harvard University, has several remarkable characteristics (Fig. 33.9). It is entirely soft, with no rigid components

FIG. 33.9 Octobot. Octobot is a soft robot inspired by the octopus. Source: Lori K. Sanders, Ryan Tully, Michael Webster, Jennifer Lewis, & Robert Wood, Harvard University.

like metal or even batteries. It is powered by a simple chemical reaction: liquid hydrogen peroxide is converted to a gas in the presence of a catalyst (in this case, platinum), providing pressure that powers movement. Finally, the robot is produced with a 3D printer.

The octobot brings together engineers, material scientists, and chemists to create a robot that is inspired by biology. This truly interdisciplinary effort is the first step toward more flexible and innovative robots for research and diverse applications.

#### Self-Assessment Questions

1. Draw a simplified animal tree of life, indicating the relationships among sponges, cnidarians, protostomes, and deuterostomes.
2. Which features distinguish sponges, cnidarians, protostomes, and deuterostomes? Place these features on the phylogeny that you drew for Self-Assessment Question 1.
3. How is cephalization an adaptation for forward locomotion?
4. Which animals are more closely related to sponges: cnidarians or bilaterians?

#### 33.2 TISSUES AND ORGANS

As we have seen, animals show a diversity of form. Nevertheless, the cells of most animals are organized into just four types of tissues: epithelial, connective, muscle, and nervous. **Tissues** are collections of cells that carry out a specific

## NEW CHAPTER 33 ANIMAL FORM, FUNCTION, AND EVOLUTIONARY HISTORY

# LIST OF NEW TOPICS & OTHER REVISIONS

The following is a detailed list of content changes. These range from small to quite substantial (an entire new chapter in the animal physiology section). Especially important changes are indicated with an asterisk ✳.

Snottites story replaced with life on Mars story ([Case 1](#))

---

✳ A rearranged discussion of DNA structure, DNA function, and process of transcription ([Chapter 3](#))

---

Chromatin structure preview removed from [Chapter 3](#) and discussed in full in [Chapter 13](#)

---

A new **How Do We Know Figure** on Anfinsen's experiment on primary and tertiary structure ([Chapter 4](#))

---

An expanded discussion of osmotic pressure ([Chapter 5](#))

---

Simplified Figure 7.3, The Four Stages of Cellular Respiration, to show only glucose and glycolysis ([Chapter 7](#))

---

A new Figure 7.18 giving an overview of the catalysis of fuel molecules other than glucose ([Chapter 7](#))

---

A redesigned bottom panel of the Visual Synthesis Figure 8.20 for clearer and more accurate inputs and outputs ([Chapter 8](#))

---

A new section illustrating how individual responses create a whole body response ([Chapter 9](#))

---

An expanded discussion of cilia ([Chapter 10](#))

---

✳ The section on nondisjunction now moved to [Chapter 11](#) and condensed ([Chapter 11](#))

---

Supercoils moved to [Section 13.4](#) from [Chapter 3](#) ([Chapter 13](#))

---

✳ Chapters on Mutation and DNA Repair and on Genetic Variation combined and condensed to more fully integrate mutations and their consequences (genotype and phenotype) ([Chapter 14](#))

- [14.1 Genotype and phenotype: mostly new section](#)
- [14.2 Nature of mutations](#)
- [14.3 Small scale mutations](#)
- [14.4 Chromosomal mutations](#)

- [14.5 DNA damage and repair](#)

---

In human genetics section, *BRCA* example replaced by *TCF7L2* diabetes example ([Chapter 15](#))

---

Extra explanation of walking through combinatorial control in plants ([Chapter 19](#))

---

Fruit fly example of Hardy-Weinberg equilibrium replaced by a continuation of Mendel's pea example ([Chapter 20](#))

---

Greenish warbler example of populations that differ in reproductive isolation replaced by briefer towhee example ([Chapter 21](#))

---

A new example and figure on the formation of a new species by hybridization: *Geospiza fortis* finches ([Chapter 21](#))

---

Figure 23.9 from the second edition removed and replaced by three new figures on different ways of using sequence data for phylogenetic reconstruction ([Chapter 23](#))

---

A new figure on the carbon cycle ([Chapter 24](#))

---

Updated bacterial and archaeal phylogenies ([Chapter 24](#))

---

Updated section on the origin of the eukaryotic cell ([Chapter 25](#))

---

Discussion of eukaryotic diversity revised in light of recent discoveries from the monumental Tara Ocean Expedition ([Chapter 25](#))

---

✳ Overall focus changed to feeding a growing population ([Case 6](#))

---

✳ A new [Section 27.1](#) compares bryophyte and vascular plant structure and function, with a focus on hydration ([Chapter 27](#))

---

A new, clearer description of xylem conduits ([Chapter 27](#))

---

✳ A completely revised and expanded explanation of the mechanism of xylem transport ([Chapter 27](#))

---

A revised description of the mechanism of filtering by the Casparian strip ([Chapter 27](#))

---

A new discussion of the unwanted effects of nitrogen fertilization ([Chapter 27](#))

---

A new paragraph on electrical signaling by plants ([Chapter 30](#))

---

✳ A new [Section 31.1](#) on the four major transitions in the evolution of plant life ([Chapter 31](#))

---

A new table on the “Diversity of Plant Life” ([Chapter 31](#))

---

Two new figures helping students integrate information from earlier chapters ([Chapter 31](#))

---

Revised phylogenies and text to reflect the uncertain relationship among the bryophytes ([Chapter 31](#))

---

✳ A new section on the evolutionary relationship of angiosperms and gymnosperms and their relative diversity ([Chapter 31](#))

---

✳ A new section on how innovations increased the efficiency of the angiosperm life cycles and xylem transport ([Chapter 31](#))

---

A revised explanation of diameter increase and vascular bundle distribution in monocot

---

stems ([Chapter 31](#))

---

More on the release of digestive enzymes from hyphae tips ([Chapter 32](#))

---

More on spore dispersal mechanisms ([Chapter 32](#))

---

✳ A new Case on biology-inspired design ([Case 7](#))

---

✳ A new chapter “Animal Form, Function, and Evolutionary History” providing an introduction to the animal physiology chapters ([Chapter 33](#))

- animal body plans
  - tissues and organs
  - introduction to homeostasis
  - evolutionary history of animals
- 

A new Case section on robots inspired by animals ([Chapter 33](#))

---

✳ The chapters on Animal Nervous Systems and Animal Sensory Systems now combined into a single chapter, with some material removed or condensed ([Chapter 34](#))

---

A new Case section on cochlear implants ([Chapter 34](#))

---

A new Case section on smart materials to heal damaged bones and improve artificial joints ([Chapter 35](#))

---

A new Case section on artificial heart valves ([Chapter 37](#))

---

New coverage of insect mandibles ([Chapter 38](#))

---

A new Case section on dialysis ([Chapter 39](#))

---

A new Case section on treating sepsis with an artificial spleen ([Chapter 41](#))

---

Two sections moved to the new chapter on Animal Form, Function, and Evolutionary History ([Chapter 42](#))

---

A new Table 43.1 summarizing Tinbergen’s four questions ([Chapter 43](#))

---

A new discussion of altruistic behavior by non-haplodiploid and non-eusocial species ([Chapter 43](#))

---

Population dynamic equations standardized and further explained ([Chapter 44](#))

---

A new density-independent factor example: replaced song sparrow example with Scottish Red Deer example ([Chapter 44](#))

---

Further explanation of life histories and tradeoffs ([Chapter 44](#))

---

✳ Rearrangements and significant revisions to island biogeography explanation ([Chapter 44](#))

---

Significant revisions to Case section on island populations and diversity ([Chapter 44](#))

---

Revision of niche concept figure and textual explanation—replaced generic pond with Connell experiment ([Chapter 45](#))

---

New example illustrating phylogenetic niche conservation: *Anolis* and *Ameiva* lizards ([Chapter 45](#))

---

New concepts of species richness and evenness in biodiversity section ([Chapter 45](#))

---

New concepts of primary and secondary succession in succession section ([Chapter 45](#))

---

✳ A new chapter on Ecosystem Ecology, [Chapter 46](#), combines ecosystem concepts such as food webs and trophic pyramids with the material on biogeochemical cycles formerly in separate chapters to present a more cohesive view of the flow of matter and energy in ecosystems.

---

New discussion of lake turnover ([Chapter 47](#))

---

# TABLE OF CONTENTS

Chapters are arranged in a familiar way to allow easy use in a range of introductory biology courses. On closer look, there are significant differences that aim to help students understand key concepts in modern biology and think like a scientist.

**Key differences** are identified by ● and **unique chapters** by ★.

|                                                                    |                                                                                      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
|--------------------------------------------------------------------|--------------------------------------------------------------------------------------|---------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------------|
| <b>PART 1 FROM CELLS TO ORGANISMS</b>                              |                                                                                      | ● <b>SIX GRAND THEMES:</b> Chapter 1 introduces six themes that act as core concepts for introductory biology. They help students to see biology not as a set of disparate facts, but instead as an integrated whole. They connect and unite the many dimensions of biology, from molecules to the environment. These themes continue to be explored throughout <i>How Life Works</i> . They include scientific inquiry, chemistry and physics, the cell, evolution, ecological systems, and human impacts.                                 |
| CHAPTER 1                                                          | Life: Chemical, Cellular, and Evolutionary Foundations                               |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| <b>CASE 1 Life's Origins: Information, Homeostasis, and Energy</b> |                                                                                      | ● <b>CASES:</b> Biology is best understood when presented using real and engaging examples as a framework for synthesizing information. Eight carefully positioned Cases help provide this framework. For example, the case about life's origins is introduced before the first set of chapters to help students understand the fundamental features of a cell, and therefore of life itself. It is then revisited in the subsequent set of chapters. This case has been updated to include recent advances in our search for life on Mars. |
| CHAPTER 2                                                          | The Molecules of Life                                                                |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 3                                                          | Nucleic Acids and Transcription                                                      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 4                                                          | Translation and Protein Structure                                                    |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 5                                                          | Organizing Principles: Lipids, Membranes, and Cell Compartments                      |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 6                                                          | Making Life Work: Capturing and Using Energy                                         |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 7                                                          | Cellular Respiration: Harvesting Energy from Carbohydrates and Other Fuel Molecules  | ● <b>CHEMISTRY:</b> After a brief chapter focusing on chemical principles, chemistry is taught in the context of biological processes in later chapters. This approach helps students to see in action the key principle.                                                                                                                                                                                                                                                                                                                   |
| CHAPTER 8                                                          | Photosynthesis: Using Sunlight to Build Carbohydrates                                |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| <b>CASE 2 Cancer: Cell Signaling, Form, and Division</b>           |                                                                                      | ● <b>THE CELL:</b> The cell is the fundamental unit of life. This concept is introduced in Chapter 1. Then, in Chapters 3–8, it is explored by highlighting three fundamental aspects of a cell—information flow (Chapters 3 and 4), homeostasis (Chapter 5), and harnessing energy (Chapters 6–8). Placing these basic points upfront allows students to start with a solid, integrated understanding of the cell.                                                                                                                         |
| CHAPTER 9                                                          | Cell Signaling                                                                       |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 10                                                         | Cell and Tissue Architecture: Cytoskeleton, Cell Junctions, and Extracellular Matrix |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 11                                                         | Cell Division: Variations, Regulation, and Cancer                                    |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| <b>CASE 3 Your Personal Genome: You, from A to T</b>               |                                                                                      | ● <b>CELL DIVISION:</b> Mitosis and meiosis are discussed in one chapter to allow students to see these two forms of cell division side-by-side and understand their similarities, differences, and evolutionary origins.                                                                                                                                                                                                                                                                                                                   |
| CHAPTER 12                                                         | DNA Replication and Manipulation                                                     |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 13                                                         | Genomes                                                                              |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 14                                                         | Mutation and Genetic Variation                                                       |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 15                                                         | Mendelian Inheritance                                                                |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 16                                                         | Inheritance of Sex Chromosomes, Linked Genes, and Organelles                         |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| ★ CHAPTER 17                                                       | The Genetic and Environmental Basis of Complex Traits                                | ● <b>GENETICS:</b> The genetics section begins with a timely case on personal genomics that is revisited in the following chapters. The chapters start with genomes and move to inheritance to provide a modern, molecular look at genetic variation and how traits are transmitted. Current techniques such as the gene editing tool CRISPR are discussed.                                                                                                                                                                                 |
| CHAPTER 18                                                         | Genetic and Epigenetic Regulation                                                    |                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                                             |
| CHAPTER 19                                                         | Genes and Development                                                                | ● <b>VARIATION:</b> Mutation and genetic variation are combined into a single chapter to help students see the interrelationship of mutation, genetic variation, and phenotypic variation.                                                                                                                                                                                                                                                                                                                                                  |

#### CASE 4 Malaria: Coevolution of Humans and a Parasite

- CHAPTER 20 Evolution: How Genotypes and Phenotypes Change Over Time
- CHAPTER 21 Species and Speciation
- CHAPTER 22 Evolutionary Patterns: Phylogeny and Fossils
- ★ CHAPTER 23 Human Origins and Evolution

### PART 2 FROM ORGANISMS TO THE ENVIRONMENT

#### CASE 5 The Human Microbiome: Diversity Within

- CHAPTER 24 Bacteria and Archaea
- CHAPTER 25 Eukaryotic Cells: Origins And Diversity
- ★ CHAPTER 26 Being Multicellular

#### CASE 6 Agriculture: Feeding a Growing Population

- CHAPTER 27 Plant Form, Function, and Evolutionary History
- CHAPTER 28 Plant Reproduction: Finding Mates and Dispersing Offspring
- CHAPTER 29 Plant Growth and Development
- ★ CHAPTER 30 Plant Defense
- CHAPTER 31 Plant Diversity
- CHAPTER 32 Fungi

#### CASE 7 Biology-Inspired Design: Using Nature to Solve Problems

- CHAPTER 33 Animal Form, Function, and Evolutionary History
- CHAPTER 34 Animal Nervous Systems
- CHAPTER 35 Animal Movement: Muscles and Skeletons
- CHAPTER 36 Animal Endocrine Systems
- CHAPTER 37 Animal Cardiovascular and Respiratory Systems
- CHAPTER 38 Animal Metabolism, Nutrition, and Digestion
- CHAPTER 39 Animal Renal Systems: Water and Waste
- CHAPTER 40 Animal Reproduction and Development
- CHAPTER 41 Animal Immune Systems
- CHAPTER 42 Animal Diversity

#### CASE 8 Conserving Biodiversity: Rainforest and Coral Reef Hotspots

- CHAPTER 43 Behavior and Behavioral Ecology
- CHAPTER 44 Population Ecology
- CHAPTER 45 Species Interactions and Communities
- CHAPTER 46 Ecosystem Ecology
- CHAPTER 47 Biomes and Global Ecology
- ★ CHAPTER 48 The Anthropocene: Humans as a Planetary Force

**EVOLUTION:** Evolution provides a thread throughout all of the chapters and resources in *How Life Works*. It is introduced in Chapter 1 as one of six core concepts of biology, allowing us to revisit evolutionary concepts and phylogenetic trees throughout. In this way, evolution provides a way for students to think broadly and in an integrated way about biology. Chapters 20–23 provide a focused discussion of key evolutionary processes, such as natural selection and speciation, and include a chapter devoted to human origins and evolution.

**PROKARYOTIC DIVERSITY:** The diversity of Bacteria and Archaea is discussed in the context of the carbon, nitrogen, and sulfur cycles, providing a conceptual backbone for understanding the tremendous diversity and ecological importance of these organisms.

**UPDATED CASE:** Case 6 has been substantially revised to highlight the challenge of feeding an ever-growing human population.

**PLANT DEFENSE:** The chapter on plant defense provides a strong ecological and case-based perspective on the strategies plants use to survive their exploitation by pathogens and herbivores.

**DIVERSITY:** Diversity follows chapters on anatomy, development, physiology, and life cycles, here and elsewhere, in order to provide a basis for understanding the groupings of organisms and to avoid presenting diversity as a list of names to memorize. When students understand the structure and function of organisms, they can understand the different groups in depth and organize them intuitively. To give instructors flexibility, brief descriptions of unfamiliar organisms and the major groups of organisms are included in the physiology chapters, and the diversity chapters include a brief review of organismal form and function.

**NEW CASE:** Biology-inspired design looks to nature to build a wide variety of tools and devices, from Velcro to prosthetic limbs. This fascinating area combines biology, engineering, and computer science, allowing students to see how different fields come together to solve complex problems. It also serves to emphasize key concepts about the anatomy and physiology of animals.

**NEW CHAPTER 33 — ANIMAL FORM, FUNCTION, AND EVOLUTIONARY HISTORY:** This chapter is new to the third edition and provides an overview of the structure, function, and evolution of animals.

**NERVOUS SYSTEMS:** The biology of nerve cells, sensory systems, and the brain are combined in a single chapter to give students an integrated perspective on these topics and concepts.

**EXPANDED ECOLOGY COVERAGE:** We continue to expand our treatment of ecological systems, one of our six grand themes. In this edition, we progress seamlessly from organisms, to populations and their interactions with other populations, to interactions among species and between species and the physical world, to global patterns of ecology, culminating in an exploration of how human activities are affecting the biosphere in the 21st century.

# PRAISE FOR *HOW LIFE WORKS*

## THE BOOK

Simply, the only textbook for this generation of students. We are no longer bearers of knowledge; the internet and Google have replaced us. So, we must teach students how science works and how we put concepts together into a coherent and meaningful way called biology. This text is designed to teach students within this new paradigm.

– Paul Moore, Bowling Green State University

Students tell me (unsolicited) that they like the textbook and that they can actually “read” it. Some say this is the first text they have actually liked reading.

– Tonya Kane, University of California, Los Angeles

This textbook does a good job of connecting concepts together and provides the student with a logical story throughout a chapter. I appreciate that and so do many of my students.

– Matthew Nusnbaum, Georgia State University

## THE CASES

The cases... provide an insightful way to introduce the topics of a particular section. In many instances they show how the text information is applicable and relevant to real life situations.

– Nilo Marin, Broward College

## ASSESSMENTS

The LearningCurve assignments have really benefited the students.  
The feedback I have gotten from students is extremely positive.

– Sally Harmych, University of Toledo

The assessment questions in general are very good and the entire system is pretty flexible and allows instructors to build a learning path and assessments that reflects the way they want their course to be taught.

– Mark Mort, University of Kansas

## VISUAL SYNTHESIS MAPS

I love the VSMs! The conceptual depth of each is really quite impressive... I am continually impressed with how deeply students dive into each VSM.

– Jeremy Rose, Oregon State University

I really like the VS maps and the ability to drill down to the level of the atom/molecular group.

– Karen Smith, University of British Columbia

# Acknowledgments

*Biology: How Life Works* is not just a book. Instead, it is an integrated set of resources to support student learning and instructor teaching in introductory biology. As a result, we work closely with a large community of authors, publishers, instructors, reviewers, and students. We would like to sincerely thank this dedicated group.

First and foremost, we thank the thousands of students we have collectively taught. Their curiosity, intelligence, and enthusiasm have been sources of motivation for all of us.

Our teachers and mentors have provided us with models of patience, creativity, and inquisitiveness that we strive to bring into our own teaching and research. They have encouraged us to be lifelong learners, teachers, and scholars.

We feel very lucky to be a partner with Macmillan Learning. From the start, our publisher has embraced our project, giving us the space to achieve something unique, while at the same time providing guidance, support, and input from a broad and diverse community of instructors and students.

We especially thank Andrew Dunaway, our program director. He has been a genuine and tireless partner in our efforts. He keeps a watchful eye on important trends in science, education, and technology, and we all deeply appreciate his enthusiasm, creativity, and vision.

Lead developmental editor Lisa Samols continues to have just the right touch—she’s a good listener, serious with a touch of humor, and quiet but persistent. Senior developmental editor Susan Moran has an eye for detail and always offers thoughtful suggestions. Both Lisa and Susan have been with us from the very start, and we really value their dedication to the project and continued partnership. Developmental editor Erin Mulligan brings a fresh eye to this edition, and has the uncanny ability to read the text like a student.

Karen Misler kept us all on schedule in a clear and firm, but also understanding and compassionate way.

Will Moore, our marketing manager, refined the story of the third edition of *How Life Works* and works tirelessly with our sales teams to bring the third edition to instructors and students everywhere.

We thank Elizabeth Geller and Martha Emry for coordinating the move from manuscript to the page, and Jill Hobbs for helping to even out the prose. We also thank Diana Blume, our design director; Hespenheide Design, our text and cover designer; and Natasha Wolfe, Design Services Manager. Together, they managed the look and feel of the book, coming up with creative solutions for page layout.

The creation and preparation of the media resources was overseen by Jennifer Driscoll Hollis, Director of Content, Life Sciences, and her team: Amber Jonker, Content Development Manager, Biology; and Mary Tibbets, Lead Content Developer, Biology. They kept all of the pieces of our ever-expanding suite of resources moving smoothly through the creation and implementation process. Michael Jones,

Media Editor, ably oversaw the updating of the animations and Visual Synthesis Maps, as well as the creation of our new 3D physiology animation and two new Visual Synthesis Maps. Emiko Paul, Creative Director, gave the Visual Synthesis Figures and Maps a sharp visual design.

Elaine Palucki, Senior Teaching and Learning Consultant, was the guiding light behind our Skills Primers and *How Do We Know* Activities. She and development editor Erin Mulligan steered the transformation of these activities into interactive learning tools.

We thank Keri deManigold and Chris Efstratiou for managing and coordinating the media and websites. They each took on this project with dedication, persistence, enthusiasm, and attention to detail that we deeply appreciate.

We would also like to thank Alexandra Hudson, Justin Jones, and Casey Blanchard for their consistent and tireless support.

Imagineering, under the patient and intelligent guidance of Mark Mykytuik, continues to provide creative, insightful art to complement, support, and reinforce the text. We also thank our illustration coordinator, Matt McAdams, for skillfully guiding our collaboration with Imagineering. Christine Buese, our photo editor, and Lisa Passmore, our photo researcher, provided us with a steady stream of stunning photos, and never gave up on those hard-to-find shots. Paul Rohloff, our workflow manager, ensured that the journey from manuscript to printing was seamless.

We would also like to acknowledge Daryl Fox, Vice President, STEM; Susan Winslow, Managing Director; and Ken Michaels, Chief Executive Officer, for their support of *How Life Works* and our unique approach.

We are extremely grateful for all of the hard work and expertise of the sales representatives, regional managers, and regional sales specialists. We have enjoyed meeting and working with this dedicated sales staff, who are the ones that ultimately put the book in the hands of instructors.

Countless reviewers made invaluable contributions to this book and deserve special thanks. From catching mistakes to suggesting new and innovative ways to organize the content, they provided substantial input to the book. They brought their collective years of teaching to the project, and their suggestions are tangible in every chapter.

Finally, we would like to thank our families. None of this would have been possible without their support, inspiration, and encouragement.

## CONTRIBUTORS, THIRD EDITION

Thank you to all the instructors who worked in collaboration with the authors and assessment authors to help write *Biology: How Life Works* assessments, activities, and other media resources.

Cynthia Giffen, University of Michigan, Skills Primers

Christine Griffin, Ohio University, Skills Primers

Sven-Uwe Heinrich, Harvard University, Visual Synthesis Maps and Timelines, content creator/editor

Benedict J. Kolber, Duquesne University, *How Do We Know* Activities, content creator/editor

Jessica Liu, Harvard University, Visual Synthesis Maps and Timelines, content creator/editor

Fulton Rockwell, Harvard University, assessment contributor

## REVIEWERS

Thank you to all the instructors who reviewed chapters, art, assessment questions, and other *Biology: How Life Works* materials.

### First Edition

Thomas Abbott, University of Connecticut

Tamarah Adair, Baylor University

Sandra Adams, Montclair State University

Jonathon Akin, University of Connecticut

Eddie Alford, Arizona State University

Chris Allen, College of the Mainland

Sylvester Allred, Northern Arizona University

Shivanthi Anandan, Drexel University

Andrew Andres, University of Nevada, Las Vegas

Michael Angilletta, Arizona State University

Jonathan Armbruster, Auburn University

Jessica Armenta, Lone Star College System

Brian Ashburner, University of Toledo

Andrea Aspbury, Texas State University

Nevin Aspinwall, Saint Louis University

Felicitas Avendano, Grand View University

Yael Avissar, Rhode Island College

Ricardo Azpiroz, Richland College

Jessica Baack, Southwestern Illinois College

Charles Baer, University of Florida

Brian Bagatto, University of Akron

Alan L. Baker, University of New Hampshire

Ellen Baker, Santa Monica College

Mitchell Balish, Miami University

Teri Balser, University of Florida

Paul Bates, University of Minnesota, Duluth

Jerome Baudry, University of Tennessee, Knoxville

Michel Baudry, University of Southern California

Mike Beach, Southern Polytechnic State University

Andrew Beall, University of North Florida

Gregory Beaulieu, University of Victoria

John Bell, Brigham Young University

Michael Bell, Richland College

Rebecca Bellone, University of Tampa

Anne Bergey, Truman State University

Laura Bermingham, University of Vermont

Aimee Bernard, University of Colorado, Denver

Annalisa Berta, San Diego State University

Joydeep Bhattacharjee, University of Louisiana, Monroe

Arlene Billock, University of Louisiana, Lafayette

Daniel Blackburn, Trinity College

Mark Blackmore, Valdosta State University

Justin Blau, New York University

Andrew Blaustein, Oregon State University

Mary Bober, Santa Monica College

Robert Bohanan, University of Wisconsin, Madison

Jim Bonacum, University of Illinois at Springfield

Laurie Bonneau, Trinity College

David Bos, Purdue University

James Bottesch, Brevard Community College

Jere Boudell, Clayton State University

Nancy Boury, Iowa State University

Matthew Brewer, Georgia State University

Mirjana Brockett, Georgia Institute of Technology

Andrew Brower, Middle Tennessee State University

Heather Bruns, Ball State University

Jill Buettner, Richland College

Stephen Burnett, Clayton State University

## **[PART 1 FROM CELLS TO ORGANISMS](#)**

### **[CHAPTER 1 LIFE: CHEMICAL, CELLULAR, AND EVOLUTIONARY FOUNDATIONS](#)**

Ralph Lee Hopkins/Getty Images

#### **[1.1 Scientific Inquiry](#)**

[Observation allows us to draw tentative explanations called hypotheses.](#)

[A hypothesis makes predictions that can be tested by observation and experiments.](#)

**[HOW DO WE KNOW?](#)** [What caused the extinction of the dinosaurs?](#)

[A theory is a general explanation of natural phenomena supported by many experiments and observations.](#)

#### **[1.2 Chemical and Physical Principles](#)**

[The living and nonliving worlds follow the same chemical rules and obey the same physical laws.](#)

[Scientific inquiry shows that living organisms come](#)

from other living organisms.

**HOW DO WE KNOW?** Can living organisms arise from nonliving matter?

### **1.3 The Cell**

**HOW DO WE KNOW?** Can microscopic life arise from nonliving matter?

Nucleic acids store and transmit information needed for growth, function, and reproduction.

Membranes define cells and spaces within cells.

Metabolism converts energy from the environment into a form that can be used by cells.

A virus is genetic material that requires a cell to carry out its functions.

### **1.4 Evolution**

Variation in populations provides the raw material for evolution.

Evolution predicts a nested pattern of relatedness among species, depicted as a tree.

Evolution can be studied by means of experiments.

**HOW DO WE KNOW?** Can evolution be demonstrated in the laboratory?

### **1.5 Ecological Systems**

Basic features of anatomy, physiology, and behavior shape ecological systems.

Ecological interactions play an important role in evolution.

## 1.6 The Human Footprint

### 🔍 CASE 1 Life's Origins: Information, Homeostasis, and Energy

## CHAPTER 2 THE MOLECULES OF LIFE

LOOK Die Bildagentur der Fotografen GmbH / Alamy

### 2.1 Properties of Atoms

Atoms consist of protons, neutrons, and electrons.

Electrons occupy regions of space called orbitals.

Elements have recurring, or periodic, chemical properties.

### 2.2 Molecules and Chemical Bonds

A covalent bond results when two atoms share electrons.

A polar covalent bond is characterized by unequal sharing of electrons.

An ionic bond forms between oppositely charged ions.

A chemical reaction involves breaking and forming chemical bonds.

### 2.3 Water

Water is a polar molecule.

A hydrogen bond is an interaction between a hydrogen atom and an electronegative atom.

Hydrogen bonds give water many unusual properties.  
pH is a measure of the concentration of protons in solution.

## **2.4 Carbon**

Carbon atoms form four covalent bonds.

Carbon-based molecules are structurally and functionally diverse.

## **2.5 Organic Molecules**

Functional groups add chemical character to carbon chains.

Proteins are composed of amino acids.

Nucleic acids encode genetic information in their nucleotide sequence.

Complex carbohydrates are made up of simple sugars.

Lipids are hydrophobic molecules.

## **2.6 Life's Origins**

 How did the molecules of life form?

The building blocks of life can be generated in the laboratory.

Experiments show how life's building blocks can form macromolecules.

**HOW DO WE KNOW?** Could the building blocks of organic molecules have been generated on the early Earth?

## **CHAPTER 3 NUCLEIC ACIDS AND TRANSCRIPTION**

Pasieka/Science Source

### **3.1 Chemical Composition and Structure of DNA**

**HOW DO WE KNOW?** Can genetic information be transmitted between two strains of bacteria?

**HOW DO WE KNOW?** Which molecule carries genetic information?

A DNA strand consists of subunits called nucleotides.

DNA is a linear polymer of nucleotides linked by phosphodiester bonds.

Cellular DNA molecules take the form of a double helix.

### **3.2 DNA Structure and Function**

DNA molecules are copied in the process of replication, which relies on base pairing.

RNA is an intermediary between DNA and protein.

### **3.3 Transcription**

RNA is a polymer of nucleotides in which the 5-carbon sugar is ribose.

**?** What kinds of nucleic acids were present in the earliest cells?

In transcription, DNA is used as a template to make complementary RNA.

Transcription starts at a promoter and ends at a terminator.

RNA polymerase adds successive nucleotides to the 3' end of the transcript.

The RNA polymerase complex is a molecular machine that opens, transcribes, and closes duplex DNA.

### **3.4 RNA Processing**

Primary transcripts in prokaryotes are translated immediately.

Primary transcripts in eukaryotes undergo several types of chemical modification.

Some RNA transcripts are processed differently from protein-coding transcripts and have functions of their own.

## **CHAPTER 4 TRANSLATION AND PROTEIN STRUCTURE**

LAGUNA DESIGN/Getty Images

### **4.1 Molecular Structure of Proteins**

Amino acids differ in their side chains.

Successive amino acids in proteins are connected by peptide bonds.

The sequence of amino acids dictates protein folding, which determines function.

Secondary structures result from hydrogen bonding in the polypeptide backbone.

Tertiary structures result from interactions between amino acid side chains.

Polypeptide subunits can come together to form quaternary structures.

Chaperones help some proteins fold properly.

**HOW DO WE KNOW?** What determines secondary and tertiary structure of proteins?

#### **4.2 Protein Synthesis**

Translation uses many molecules found in all cells.

The genetic code shows the correspondence between codons and amino acids.

**HOW DO WE KNOW?** How was the genetic code deciphered?

Translation consists of initiation, elongation, and termination.

 How did the genetic code originate?

#### **4.3 Protein Origins and Evolution**

Most proteins are composed of modular folding domains.

Amino acid sequences evolve through mutation and selection.

 **VISUAL SYNTHESIS Gene Expression**

### **CHAPTER 5 ORGANIZING PRINCIPLES: LIPIDS, MEMBRANES, AND CELL COMPARTMENTS**

Dr. Jeremy Burgess/Science Source.

## **5.1 Structure of Cell Membranes**

Cell membranes are composed of two layers of lipids.

❓ How did the first cell membranes form?

Cell membranes are dynamic.

Proteins associate with cell membranes in different ways.

## **5.2 Movement In and Out of Cells**

**HOW DO WE KNOW?** Do proteins move in the plane of the membrane?

The plasma membrane maintains homeostasis.

Passive transport involves diffusion.

Primary active transport uses the energy of ATP.

Secondary active transport is driven by an electrochemical gradient.

Many cells maintain size and composition using active transport.

The cell wall provides another means of maintaining cell shape.

## **5.3 Internal Organization of Cells**

Eukaryotes and prokaryotes differ in internal organization.

Prokaryotic cells lack a nucleus and extensive internal

compartmentalization.

Eukaryotic cells have a nucleus and specialized internal structures.

## **5.4 The Endomembrane System**

The endomembrane system compartmentalizes the cell.

The nucleus houses the genome and is the site of RNA synthesis.

The endoplasmic reticulum is involved in protein and lipid synthesis.

The Golgi apparatus modifies and sorts proteins and lipids.

Lysosomes degrade macromolecules.

Protein sorting directs proteins to their proper location in or out of the cell.

## **5.5 Mitochondria and Chloroplasts**

Mitochondria provide the eukaryotic cell with most of its usable energy.

Chloroplasts capture energy from sunlight.

# **CHAPTER 6 MAKING LIFE WORK: CAPTURING AND USING ENERGY**

Purestock/Getty Images

## **6.1 An Overview of Metabolism**

Organisms can be classified according to their energy and carbon sources.

Metabolism is the set of chemical reactions that sustain life.

## **6.2 Kinetic and Potential Energy**

Kinetic energy and potential energy are two forms of energy.

Chemical energy is a form of potential energy.

ATP is a readily accessible form of cellular energy.

## **6.3 Laws of Thermodynamics**

The first law of thermodynamics: energy is conserved.

The second law of thermodynamics: energy transformations always result in an increase in disorder in the universe.

## **6.4 Chemical Reactions**

A chemical reaction occurs when molecules interact.

The laws of thermodynamics determine whether a chemical reaction requires or releases energy available to do work.

The hydrolysis of ATP is an exergonic reaction.

Non-spontaneous reactions are often coupled to spontaneous reactions.

## **6.5 Enzymes and the Rate of Chemical Reactions**

Enzymes reduce the activation energy of a chemical reaction.

Enzymes form a complex with reactants and products.

Enzymes are highly specific.

Enzyme activity can be influenced by inhibitors and activators.

Allosteric enzymes regulate key metabolic pathways.

**HOW DO WE KNOW? Do enzymes form complexes with substrates?**

❓ What naturally occurring elements might have spurred the first reactions that led to life?

## **CHAPTER 7 CELLULAR RESPIRATION: HARVESTING ENERGY FROM CARBOHYDRATES AND OTHER FUEL MOLECULES**

Steve Satushek/Getty Images

### **7.1 An Overview of Cellular Respiration**

Cellular respiration uses chemical energy stored in molecules such as carbohydrates and lipids to produce ATP.

ATP is generated by substrate-level phosphorylation and oxidative phosphorylation.

Redox reactions play a central role in cellular respiration.

Cellular respiration occurs in four stages.

### **7.2 Glycolysis**

Glycolysis is the partial breakdown of glucose.

### **7.3 Pyruvate Oxidation**

The oxidation of pyruvate connects glycolysis to the citric acid cycle.

### **7.4 The Citric Acid Cycle**

The citric acid cycle produces ATP and reduced electron carriers.

❓ What were the earliest energy-harnessing reactions?

### **7.5 The Electron Transport Chain and Oxidative Phosphorylation**

The electron transport chain transfers electrons and pumps protons.

The proton gradient is a source of potential energy.

ATP synthase converts the energy of the proton gradient into the energy of ATP.

**HOW DO WE KNOW?** Can a proton gradient drive the synthesis of ATP?

### **7.6 Anaerobic Metabolism**

Fermentation extracts energy from glucose in the absence of oxygen.

❓ How did early cells meet their energy requirements?

### **7.7 Metabolic Integration**

Excess glucose is stored as glycogen in animals and starch in plants.

Sugars other than glucose contribute to glycolysis.

Fatty acids and proteins are useful sources of energy.

The intracellular level of ATP is a key regulator of

cellular respiration.

Exercise requires several types of fuel molecules and the coordination of metabolic pathways.

## **CHAPTER 8 PHOTOSYNTHESIS: USING SUNLIGHT TO BUILD CARBOHYDRATES**

ooyoo/Getty Images

### **8.1 An Overview of Photosynthesis**

Photosynthesis is widely distributed.

Photosynthesis is a redox reaction.

**HOW DO WE KNOW?** Does the oxygen released by photosynthesis come from H<sub>2</sub>O or CO<sub>2</sub>?

The photosynthetic electron transport chain takes place in specialized membranes.

### **8.2 The Calvin Cycle**

The incorporation of CO<sub>2</sub> is catalyzed by the enzyme rubisco.

NADPH is the reducing agent of the Calvin cycle.

**HOW DO WE KNOW?** How is CO<sub>2</sub> incorporated into carbohydrates?

The regeneration of RuBP requires ATP.

The steps of the Calvin cycle were determined using radioactive CO<sub>2</sub>.

Carbohydrates are stored in the form of starch.

### **8.3 Capturing Sunlight into Chemical Forms**

Chlorophyll is the major entry point for light energy in photosynthesis.

Antenna chlorophyll passes light energy to reaction centers.

The photosynthetic electron transport chain connects two photosystems.

**HOW DO WE KNOW?** Do chlorophyll molecules operate on their own or in groups?

The accumulation of protons in the thylakoid lumen drives the synthesis of ATP.

Cyclic electron transport increases the production of ATP.

### **8.4 Photosynthetic Challenges**

Excess light energy can cause damage.

Photorespiration leads to a net loss of energy and carbon.

Photosynthesis captures just a small percentage of incoming solar energy.

### **8.5 The Evolution of Photosynthesis**

 How did early cells use sunlight to meet their energy requirements?

The ability to use water as an electron donor in photosynthesis evolved in cyanobacteria.

Eukaryotic organisms are believed to have gained photosynthesis by endosymbiosis.

**VS** VISUAL SYNTHESIS Harnessing Energy:  
Photosynthesis and Cellular Respiration

**?** CASE 2 Cancer: Cell Signaling, Form, and Division

CHAPTER 9 CELL SIGNALING

Quest/Science Source

**9.1 Principles of Cell Signaling**

Cells communicate using chemical signals that bind to receptors.

Signaling involves receptor activation, signal transduction, response, and termination.

The response of a cell to a signaling molecule depends on the cell type.

**9.2 Distance Between Cells**

Endocrine signaling acts over long distances.

Signaling can occur over short distances.

Signaling can occur by direct cell–cell contact.

**HOW DO WE KNOW?** Where do growth factors come from?

**9.3 Signaling Receptors**

Receptors for polar signaling molecules are located on the cell surface.

Receptors for nonpolar signaling molecules are located

in the interior of the cell.

Cell-surface receptors act like molecular switches.

### **9.4 G Protein-Coupled Receptors**

The first step in cell signaling is receptor activation.

Signals are often amplified in the cytosol.

Signals lead to a cellular response.

Signaling pathways are eventually terminated.

### **9.5 Receptor Kinases**

Receptor kinases phosphorylate each other, activate intracellular signaling pathways, lead to a response, and are terminated.

❓ How do cell signaling errors lead to cancer?

Signaling pathways are integrated to produce a response in a cell.

## **CHAPTER 10 CELL AND TISSUE ARCHITECTURE: CYTOSKELETON, CELL JUNCTIONS, AND EXTRACELLULAR MATRIX**

F. Fox/AGE Fotostock

### **10.1 Tissues and Organs**

Tissues and organs are communities of cells.

The structure of skin relates to its function.

### **10.2 The Cytoskeleton**

Microtubules and microfilaments are polymers of protein subunits.

Microtubules and microfilaments are dynamic structures.

Motor proteins associate with microtubules and microfilaments to cause movement.

Intermediate filaments are polymers of proteins that vary according to cell type.

The cytoskeleton is an ancient feature of cells.

### **10.3 Cell Junctions**

Cell adhesion molecules allow cells to attach to other cells and to the extracellular matrix.

Anchoring junctions connect adjacent cells and are reinforced by the cytoskeleton.

Tight junctions prevent the movement of substances through the space between cells.

Molecules pass between cells through communicating junctions.

### **10.4 The Extracellular Matrix**

The extracellular matrix of plants is the cell wall.

The extracellular matrix is abundant in connective tissues of animals.

❓ How do cancer cells spread throughout the body?

Extracellular matrix proteins influence cell shape and gene expression.

**HOW DO WE KNOW?** Can extracellular matrix proteins influence gene expression?

## CHAPTER 11 CELL DIVISION: VARIATION, REGULATION, AND CANCER

Dr. Torsten Wittmann/Science Source

### 11.1 Cell Division

Prokaryotic cells divide by binary fission.

Eukaryotic cells divide by mitotic cell division.

The cell cycle describes the life cycle of a eukaryotic cell.

### 11.2 Mitotic Cell Division

The DNA of eukaryotic cells is organized as chromosomes.

Prophase: Chromosomes condense and become visible.

Prometaphase: Chromosomes attach to the mitotic spindle.

Metaphase: Chromosomes align as a result of dynamic changes in the mitotic spindle.

Anaphase: Sister chromatids fully separate.

Telophase: Nuclear envelopes re-form around newly segregated chromosomes.

The parent cell divides into two daughter cells by cytokinesis.

### 11.3 Meiotic Cell Division

Pairing of homologous chromosomes is unique to meiosis.

Crossing over between DNA molecules results in exchange of genetic material.

The first meiotic division reduces the chromosome number.

The second meiotic division resembles mitosis.

Division of the cytoplasm often differs between the sexes.

Meiosis is the basis of sexual reproduction.

#### **11.4 Nondisjunction**

Nondisjunction in meiosis results in extra or missing chromosomes.

Some human disorders result from nondisjunction.

Extra or missing sex chromosomes have fewer effects than extra autosomes.

#### **11.5 Cell Cycle Regulation**

Protein phosphorylation controls passage through the cell cycle.

**HOW DO WE KNOW?** How is progression through the cell cycle controlled?

Different cyclin–CDK complexes regulate each stage of the cell cycle.

Cell cycle progression requires successful passage through multiple checkpoints.

#### **11.6 Cancer**

? What genes are involved in cancer?

Oncogenes promote cancer.

Proto-oncogenes are genes that when mutated may cause cancer.

Tumor suppressors block specific steps in the development of cancer.

**HOW DO WE KNOW? Can a virus cause cancer?**

Most cancers require the accumulation of multiple mutations.

**VS VISUAL SYNTHESIS Cellular Communities**

**? CASE 3 Your Personal Genome: You, from A to T**

## **CHAPTER 12 DNA REPLICATION AND MANIPULATION**

Andrea Danti/Shutterstock

### **12.1 DNA Replication**

During DNA replication, the parental strands separate and new partners are made.

New DNA strands grow by the addition of nucleotides to the 3' end.

**HOW DO WE KNOW? How is DNA replicated?**

In replicating DNA, one daughter strand is synthesized continuously and the other in a series of short pieces.

A small stretch of RNA is needed to begin synthesis of a new DNA strand.

Synthesis of the leading and lagging strands is coordinated.

DNA polymerase is self-correcting because of its proofreading function.

## **12.2 Replication of Chromosomes**

Replication of DNA in chromosomes starts at many places almost simultaneously.

Telomerase restores tips of linear chromosomes shortened during DNA replication.

## **12.3 DNA Techniques**

The polymerase chain reaction selectively amplifies regions of DNA.

Electrophoresis separates DNA fragments by size.

Restriction enzymes cleave DNA at particular short sequences.

DNA strands can be separated and brought back together again.

DNA sequencing makes use of the principles of DNA replication.

❓ What new technologies are used to sequence your personal genome?

## **12.4 Genetic Engineering**

Recombinant DNA combines DNA molecules from two or more sources.

Recombinant DNA is the basis of genetically modified organisms.

DNA editing can be used to alter gene sequences almost at will.

## **CHAPTER 13 GENOMES**

### **13.1 Genome Sequencing**

Complete genome sequences are assembled from smaller pieces.

Sequences that are repeated complicate sequence assembly.

**HOW DO WE KNOW?** How are whole genomes sequenced?

**?** Why sequence your personal genome?

### **13.2 Genome Annotation**

Genome annotation identifies various types of sequence.

Genome annotation includes searching for sequence motifs.

Comparison of genomic DNA with messenger RNA reveals the intron–exon structure of genes.

An annotated genome summarizes knowledge, guides research, and reveals evolutionary relationships among

organisms.

The HIV genome illustrates the utility of genome annotation and comparison.

### **13.3 Genes, Genomes, and Organismal Complexity**

Gene number is not a good predictor of biological complexity.

Viruses, bacteria, and archaeons have small, compact genomes.

Among eukaryotes, no relationship exists between genome size and organismal complexity.

About half of the human genome consists of transposable elements and other types of repetitive DNA.

### **13.4 Organization of Genomes**

Bacterial cells package their DNA as a nucleoid composed of many loops.

Eukaryotic cells package their DNA as one molecule per chromosome.

The human genome consists of 22 pairs of chromosomes and two sex chromosomes.

Organelle DNA forms nucleoids that differ from those in bacteria.

### **13.5 Viruses and Viral Genomes**

Viruses can be classified by their genomes.

The host range of a virus is determined by viral and host surface proteins.

Viruses have diverse sizes and shapes.

## CHAPTER 14 MUTATION AND GENETIC VARIATION

Tetra Images/Getty Images

### 14.1 Genotype and Phenotype

Genotype is the genetic makeup of a cell or organism, and the phenotype is its observed characteristics.

Some genetic differences are harmful.

Some genetic differences are neutral.

A few genetic differences are beneficial.

The effect of a mutation may depend on the genotype and environment.

### 14.2 The Nature of Mutations

Mutation of individual nucleotides is rare, but mutation across the genome is common.

Only germ-line mutations are transmitted to progeny.

❓ What can your personal genome tell you about your genetic risk factors for cancer?

Mutations are random with regard to an organism's needs.

**HOW DO WE KNOW?** Do mutations occur randomly, or are they directed by the environment?

### 14.3 Small-Scale Mutations

Point mutations are changes in a single nucleotide.

The effect of a point mutation depends in part on where in the genome it occurs.

Small insertions and deletions involve several nucleotides.

Some mutations are due to the insertion of a transposable element.

**HOW DO WE KNOW?** What causes sectoring in corn kernels?

#### **14.4 Chromosomal Mutations**

Duplications and deletions result in gain or loss of DNA.

Gene families arise from gene duplication and divergence.

Copy-number variation constitutes a significant proportion of genetic variation.

Tandem repeats are useful in DNA typing.

An inversion has a chromosomal region reversed in orientation.

A reciprocal translocation joins segments from nonhomologous chromosomes.

#### **14.5 DNA Damage and Repair**

DNA damage can affect both DNA backbone and bases.

Most DNA damage is corrected by specialized repair enzymes.

### **CHAPTER 15 MENDELIAN INHERITANCE**

Edoma/Getty Images

### **15.1 Early Theories of Inheritance**

Early theories of heredity predicted the transmission of acquired characteristics.

Belief in blending inheritance discouraged studies of hereditary transmission.

### **15.2 Foundations of Modern Transmission Genetics**

Mendel's experimental organism was the garden pea.

In crosses, one of the traits was dominant in the offspring.

### **15.3 Segregation**

Genes come in pairs that segregate in the formation of reproductive cells.

The principle of segregation was tested by predicting the outcome of crosses.

A testcross is a mating to an individual with the homozygous recessive genotype.

Segregation of alleles reflects the separation of chromosomes in meiosis.

Dominance is not universally observed.

The principles of transmission genetics are statistical and are stated in terms of probabilities.

Mendelian segregation preserves genetic variation.

## **15.4 Independent Assortment**

Independent assortment is observed when genes segregate independently of one another.

Independent assortment reflects the random alignment of chromosomes in meiosis

Phenotypic ratios can be modified by interactions between genes.

**HOW DO WE KNOW?** How are single-gene traits inherited?

## **15.5 Human Genetics**

Dominant traits appear in every generation.

Recessive traits skip generations.

Many genes have multiple alleles.

Incomplete penetrance and variable expression can obscure inheritance patterns.

 How do genetic tests identify disease risk factors?

## **CHAPTER 16 INHERITANCE OF SEX CHROMOSOMES, LINKED GENES, AND ORGANELLES**

FatCamera/Getty Images

## **16.1 The X and Y Chromosomes**

In many animals, sex is genetically determined and

associated with chromosomal differences.

Segregation of the sex chromosomes predicts a 1 : 1 ratio of females to males.

## **16.2 Inheritance of Genes in the X Chromosome**

X-linked inheritance was discovered through studies of male fruit flies with white eyes.

Genes in the X chromosome exhibit a crisscross inheritance pattern.

X-linkage provided the first experimental evidence that genes are in chromosomes.

Genes in the X chromosome show characteristic patterns in human pedigrees.

## **16.3 Genetic Linkage**

Nearby genes in the same chromosome show linkage.

The frequency of recombination is a measure of the genetic distance between linked genes.

Genetic mapping assigns a location to each gene along a chromosome.

Genetic risk factors for disease can be localized by genetic mapping.

**HOW DO WE KNOW?** Can recombination be used to construct a genetic map of a chromosome?

## **16.4 Inheritance of Genes in the Y Chromosome**

Y-linked genes are transmitted from father to son.

❓ How can the Y chromosome be used to trace ancestry?

## **16.5 Inheritance of Mitochondrial and Chloroplast DNA**

Mitochondrial and chloroplast genomes often show uniparental inheritance.

Maternal inheritance is characteristic of mitochondrial diseases.

❓ How can mitochondrial DNA be used to trace ancestry?

## **CHAPTER 17 THE GENETIC AND ENVIRONMENTAL BASIS OF COMPLEX TRAITS**

Ryan McVay/Getty Images

### **17.1 Heredity and Environment**

Complex traits are affected by the environment.

Complex traits are affected by multiple genes.

The relative importance of genes and environment can be determined by differences among individuals.

Genetic and environmental effects can interact in unpredictable ways.

### **17.2 Resemblance Among Relatives**

For complex traits, offspring resemble parents but show regression toward the mean.

Heritability is the proportion of the total variation due to genetic differences among individuals.

### **17.3 Twin Studies**

Twin studies help separate the effects of genes and environment in differences among individuals.

**HOW DO WE KNOW?** What is the relative importance of genes and of the environment for complex traits?

### **17.4 Complex Traits in Health and Disease**

Most common diseases and birth defects are affected by many genes, each with a relatively small effect.

Human height is affected by hundreds of genes.

❓ Can personalized medicine lead to effective treatments of common diseases?

## **CHAPTER 18 GENETIC AND EPIGENETIC REGULATION**

Lawrence Berkeley National  
Laboratory/Science Source

### **18.1 Chromatin to Messenger RNA in Eukaryotes**

Gene expression can be influenced by chemical modification of DNA or histones.

Gene expression can be regulated at the level of an entire chromosome.

Transcription is a key control point in gene expression.

RNA processing is also important in gene regulation.

## 18.2 Messenger RNA to Phenotype in Eukaryotes

Small regulatory RNAs inhibit translation or promote mRNA degradation.

Translational regulation controls the rate, timing, and location of protein synthesis.

Protein structure and chemical modification modulate protein effects on phenotype.

 How do lifestyle choices affect expression of your personal genome?

## 18.3 Transcriptional Regulation in Prokaryotes

Transcriptional regulation can be positive or negative.

Lactose utilization in *E. coli* is the pioneering example of transcriptional regulation.

**HOW DO WE KNOW?** How does lactose lead to the production of active  $\beta$ -galactosidase enzyme?

The repressor protein binds with the operator and prevents transcription, but not in the presence of lactose.

The function of the lactose operon was revealed by genetic studies.

The lactose operon is also positively regulated by CRP–cAMP.

Transcriptional regulation determines the outcome of infection by a bacterial virus.

 **VISUAL SYNTHESIS Virus: A Genome in Need of a Cell**

## CHAPTER 19 GENES AND DEVELOPMENT

Perennou Nuridsany/Science Source

## **19.1 Genetic Basis of Development**

The fertilized egg is a totipotent cell.

Cellular differentiation increasingly restricts alternative fates.

**HOW DO WE KNOW?** How do stem cells lose their ability to differentiate into any cell type?

❓ Can cells with your personal genome be reprogrammed for new therapies?

## **19.2 Hierarchical Control**

*Drosophila* development proceeds through egg, larval, and adult stages.

The egg is a highly polarized cell.

Development proceeds by progressive regionalization and specification.

Homeotic genes determine where different body parts develop in the organism.

## **19.3 Master Regulators**

Animals have evolved a wide variety of eyes.

*Pax6* is a master regulator of eye development.

## **19.4 Combinatorial Control**

Floral differentiation is a model for plant development.

The identity of the floral organs is determined by combinatorial control.

## **19.5 Cell Signaling in Development**

A signaling molecule can cause multiple responses in the cell.

Developmental signals are amplified and expanded.

## **VISUAL SYNTHESIS Genetic Variation and Inheritance**

### **? CASE 4 Malaria: Coevolution of Humans and a Parasite**

## **CHAPTER 20 EVOLUTION: HOW GENOTYPES AND PHENOTYPES CHANGE OVER TIME**

Andrew Berry

## **20.1 Genetic Variation**

Population genetics is the study of patterns of genetic variation.

Mutation and recombination are the two sources of genetic variation.

## **20.2 Measuring Genetic Variation**

To understand patterns of genetic variation, we require information about allele frequencies.

Early population geneticists relied on observable traits and gel electrophoresis to measure variation.

DNA sequencing is the gold standard for measuring genetic variation.

**HOW DO WE KNOW?** How did gel electrophoresis allow us to detect genetic variation?

### **20.3 Evolution and the Hardy–Weinberg Equilibrium**

Evolution is a change in allele or genotype frequency over time.

The Hardy–Weinberg equilibrium describes situations in which allele and genotype frequencies do not change.

The Hardy–Weinberg equilibrium relates allele frequencies and genotype frequencies.

The Hardy–Weinberg equilibrium is the starting point for population genetic analysis.

### **20.4 Natural Selection**

Natural selection brings about adaptations.

The Modern Synthesis combines Mendelian genetics and Darwinian evolution.

Natural selection increases the frequency of advantageous mutations and decreases the frequency of deleterious mutations.

❓ Which genetic differences have made some individuals more and some less susceptible to malaria?

Natural selection can be stabilizing, directional, or disruptive.

**HOW DO WE KNOW?** How far can artificial selection be taken?

Sexual selection increases an individual's reproductive

success.

## **20.5 Non-Adaptive Mechanisms of Evolution**

Genetic drift is a change in allele frequency due to chance.

Genetic drift has a large effect in small populations.

Migration reduces genetic variation between populations.

Mutation increases genetic variation.

Nonrandom mating alters genotype frequencies without affecting allele frequencies.

## **20.6 Molecular Evolution**

The molecular clock relates the amount of sequence difference between species and the time since the species diverged.

The rate of the molecular clock varies.

## **CHAPTER 21 SPECIES AND SPECIATION**

Zoonar GmbH/Alamy

## **21.1 The Biological Species Concept**

Species are reproductively isolated from other species.

The BSC is more useful in theory than in practice.

The BSC does not apply to asexual or extinct organisms.

Hybridization complicates the BSC.

Ecology and evolution can extend the BSC.

## **21.2 Reproductive Isolation**

Pre-zygotic isolating factors occur before egg fertilization.

Post-zygotic isolating factors occur after egg fertilization.

## **21.3 Speciation**

Speciation is a by-product of the genetic divergence of separated populations.

Allopatric speciation is speciation that results from the geographical separation of populations.

Dispersal and vicariance can isolate populations from each other.

**HOW DO WE KNOW?** Can vicariance cause speciation?

Co-speciation is speciation that occurs in response to speciation in another species.

 How did malaria come to infect humans?

Sympatric populations—those in the same place—may undergo speciation.

Speciation can occur instantaneously.

Speciation can occur with or without natural selection.

 **VISUAL SYNTHESIS Speciation**

## **CHAPTER 22 EVOLUTIONARY PATTERNS: PHYLOGENY AND FOSSILS**

Dudley Museums Service

## **22.1 Reading a Phylogenetic Tree**

Phylogenetic trees provide hypotheses of evolutionary relationships.

The search for sister groups lies at the heart of phylogenetics.

A monophyletic group consists of a common ancestor and all its descendants.

Taxonomic classifications are information storage and retrieval systems.

## **22.2 Building a Phylogenetic Tree**

Homology is similarity by common descent.

Shared derived characters enable biologists to reconstruct evolutionary history.

The simplest tree is often favored among multiple possible trees.

Molecular data complement comparative morphology in reconstructing phylogenetic history.

Phylogenetic trees can help solve practical problems.

**HOW DO WE KNOW?** Did an HIV-positive dentist spread the AIDS virus to his patients?

## **22.3 The Fossil Record**

Fossils provide unique information.

Fossils provide a selective record of past life.

Geologic data indicate the age and environmental setting of fossils.

Fossils can contain unique combinations of characters.

**HOW DO WE KNOW?** Do fossils bridge the evolutionary gap between fish and tetrapod vertebrates?

Rare mass extinctions have altered the course of evolution.

## **22.4 Comparing Evolution's Two Great Patterns**

Phylogeny and fossils complement each other.

Agreement between phylogenies and the fossil record provides strong evidence of evolution.

## **CHAPTER 23 HUMAN ORIGINS AND EVOLUTION**

DLILLC/Corbis/VCG/Getty Images

### **23.1 The Great Apes**

Comparative anatomy shows that the human lineage branches off the great apes tree.

Molecular analysis reveals that the human lineage split from the chimpanzee lineage about 5–7 million years ago.

**HOW DO WE KNOW?** How closely related are humans and chimpanzees?

The fossil record gives us direct information about our evolutionary history.

### **23.2 African Origins**

Studies of mitochondrial DNA reveal that modern humans evolved in Africa relatively recently.

**HOW DO WE KNOW?** When and where did the most recent common ancestor of all living humans live?

Studies of the Y chromosome provide independent evidence for a recent origin of modern humans.

Neanderthals disappear from the fossil record as modern humans appear, but have contributed to the modern human gene pool.

### **23.3 Human Traits**

Bipedalism was a key innovation.

Adult humans share many features with juvenile chimpanzees.

Humans have large brains relative to body size.

The human and chimpanzee genomes help us identify genes that make us human.

### **23.4 Human Genetic Variation**

Humans have very little genetic variation.

The prehistory of humans influenced the distribution of genetic variation.

The recent spread of modern humans means that there are few genetic differences between groups.

Some human differences have likely arisen by natural

selection.

⑦ Which human genes are under selection for resistance to malaria?

### **23.5 Culture, Language, and Consciousness**

Culture changes rapidly.

Is culture uniquely human?

Is language uniquely human?

Is consciousness uniquely human?

## **PART 2 FROM ORGANISMS TO THE ENVIRONMENT**

⑦ **CASE 5 The Human Microbiome: Diversity Within**

### **CHAPTER 24 BACTERIA AND ARCHAEA**

STEVE GSCHMEISSNER/SCIENCE  
PHOTO LIBRARY/Getty Images

### **24.1 Two Prokaryotic Domains**

The bacterial cell is small but powerful.

Diffusion limits cell size in bacteria.

Horizontal gene transfer promotes genetic diversity in bacteria.

Archaea form a second prokaryotic domain.

### **24.2 An Expanded Carbon Cycle**

Many photosynthetic bacteria do not produce oxygen.

Many bacteria respire without oxygen.

Photoheterotrophs obtain energy from light but obtain carbon from preformed organic molecules.

Chemoautotrophy is a uniquely prokaryotic metabolism.

### **24.3 Sulfur and Nitrogen Cycles**

Bacteria and archaeons dominate Earth's sulfur cycle.

The nitrogen cycle is also driven by bacteria and archaeons.

### **24.4 Bacterial Diversity**

Bacterial phylogeny is a work in progress.

**HOW DO WE KNOW?** How many kinds of bacterium live in the oceans?

What, if anything, is a bacterial species?

Proteobacteria are the most diverse bacteria.

The gram-positive bacteria include organisms that cause and cure disease.

Photosynthesis is widely distributed on the bacterial tree.

### **24.5 Archaeal Diversity**

The archaeal tree has anaerobic, hyperthermophilic organisms near its base.

The Archaea include several groups of acid-loving microorganisms.

Only Archaea produce methane as a by-product of energy metabolism.

One group of the Euryarchaeota thrives in extremely salty environments.

Thaumarchaeota may be the most abundant cells in the

deep ocean.

**HOW DO WE KNOW?** How abundant are archaeons in the oceans?

## **24.6 The Evolutionary History of Prokaryotes**

Life originated early in our planet's history.

Prokaryotes have coevolved with eukaryotes.

❓ How do intestinal bacteria influence human health?

## **CHAPTER 25 EUKARYOTIC CELLS: ORIGINS AND DIVERSITY**

Lebendkulturen.de/Shutterstock

### **25.1 A Review of the Eukaryotic Cell**

Internal protein scaffolding and dynamic membranes organize the eukaryotic cell.

In eukaryotic cells, energy metabolism is localized in mitochondria and chloroplasts.

The organization of the eukaryotic genome also helps explain eukaryotic diversity.

Sex promotes genetic diversity in eukaryotes and gives rise to distinctive life cycles.

### **25.2 Eukaryotic Origins**

❓ What role did symbiosis play in the origin of chloroplasts?

**HOW DO WE KNOW?** What is the evolutionary origin of chloroplasts?

❓ What role did symbiosis play in the origin of mitochondria?

❓ How did the eukaryotic cell originate?

In the oceans, many single-celled eukaryotes harbor symbiotic bacteria.

### **25.3 Eukaryotic Diversity**

Our own group, the opisthokonts, is the most diverse eukaryotic superkingdom.

Amoebozoans include slime molds that produce multicellular structures.

Archaeplastids, which include land plants, are photosynthetic organisms.

Stramenopiles, alveolates, and rhizarians dominate eukaryotic diversity in the oceans.

**HOW DO WE KNOW?** How did photosynthesis spread through the Eukarya?

Photosynthesis spread through eukaryotes by repeated endosymbioses involving eukaryotic algae.

### **25.4 The Fossil Record of Protists**

Fossils show that eukaryotes existed at least 1800 million years ago.

Protists have continued to diversify during the age of animals.

## **CHAPTER 26 BEING MULTICELLULAR**

irawansubingarphotography/  
Getty Images

## **26.1 The Phylogenetic Distribution of Multicellular Organisms**

Simple multicellularity is widespread among eukaryotes.

Complex multicellularity evolved several times.

## **26.2 Diffusion and Bulk Flow**

Diffusion is effective only over short distances.

Animals achieve large size by circumventing limits imposed by diffusion.

Complex multicellular organisms have structures specialized for bulk flow.

## **26.3 How to Build a Multicellular Organism**

Complex multicellularity requires adhesion between cells.

**HOW DO WE KNOW?** How do bacteria influence the life cycles of choanoflagellates?

How did animal cell adhesion originate?

Complex multicellularity requires communication between cells.

Complex multicellularity requires a genetic program for coordinated growth and cell differentiation.

## **26.4 Plants Versus Animals**

Cell walls shape patterns of growth and development in plants.

Animal cells can move relative to one another.

## **26.5 The Evolution of Complex Multicellularity**

Fossil evidence of complex multicellular organisms is first observed in rocks deposited 575–555 million years ago.

Oxygen is necessary for complex multicellular life.

Land plants evolved from green algae that could carry out photosynthesis on land.

Regulatory genes played an important role in the evolution of complex multicellular organisms.

**HOW DO WE KNOW?** What controls color pattern in butterfly wings?

### **❓ CASE 6 Agriculture: Feeding a Growing Population**

## **CHAPTER 27 PLANT FORM, FUNCTION, AND EVOLUTIONARY HISTORY**

Frank Krahmer/Getty Images

### **27.1 Photosynthesis on Land**

Land plants share many cellular features with green algae.

Bryophytes rely on surface water for hydration.

Water pulled from the soil moves through vascular plants by bulk flow.

Vascular plants produce four major organ types.

## **27.2 Carbon Dioxide Gain and Water Loss**

CO<sub>2</sub> uptake results in water loss.

The cuticle restricts water loss from leaves but inhibits the uptake of CO<sub>2</sub>.

Stomata allow leaves to regulate water loss and carbon gain.

CAM plants use nocturnal CO<sub>2</sub> storage to avoid water loss during the day.

C<sub>4</sub> plants suppress photorespiration by concentrating CO<sub>2</sub> in bundle-sheath cells.

**HOW DO WE KNOW?** Does C<sub>4</sub> photosynthesis suppress photorespiration?

## **27.3 Water Transport**

Xylem provides a low-resistance pathway for the movement of water.

Water is pulled through xylem by an evaporative pump.

**HOW DO WE KNOW?** Do plants generate negative pressures?

Xylem transport is at risk of conduit collapse and cavitation.

## **27.4 Transport of Carbohydrates**

Phloem transports carbohydrates from sources to sinks.

Carbohydrates are pushed through phloem by an osmotic

pump.

Phloem feeds both the plant and the rhizosphere.

## **27.5 Uptake of Water and Nutrients**

Plants obtain nutrients from the soil.

Nutrient uptake by roots is highly selective.

Nutrient uptake requires energy.

Mycorrhizae enhance nutrient uptake.

Symbiotic nitrogen-fixing bacteria supply nitrogen to both plants and ecosystems.

❓ How has nitrogen availability influenced agricultural productivity?

## **CHAPTER 28 PLANT REPRODUCTION: FINDING MATES AND DISPERSING YOUNG**

Rogelio Moreno/SCIENCE PHOTO  
LIBRARY/Science Source

### **28.1 Alternation of Generations**

The algal sister groups of land plants have one multicellular generation in their life cycle.

Land plants have two multicellular generations in their life cycle.

Bryophytes illustrate how the alternation of generations allows the dispersal of spores in the air.

Dispersal enhances reproductive fitness in several ways.

Spore-dispersing vascular plants have free-living gametophytes and sporophytes.

## **28.2 Seed Plants**

The seed plant life cycle is distinguished by four major steps.

Pine trees illustrate how the transport of pollen in air allows fertilization to occur in the absence of external sources of water.

Seeds enhance the establishment of the next sporophyte generation.

## **28.3 Flowering Plants**

Flowers are reproductive shoots specialized for the transfer and receipt of pollen.

The diversity of floral morphology is related to modes of pollination.

**HOW DO WE KNOW?** How do long nectar spurs evolve?

Angiosperms have mechanisms to increase outcrossing.

Angiosperms delay provisioning their ovules until after fertilization.

Fruits enhance the dispersal of seeds.

❓ How did scientists increase crop yields during the Green Revolution?

## **28.4 Asexual Reproduction**

Asexually produced plants disperse with and without seeds.

## **CHAPTER 29 PLANT GROWTH AND DEVELOPMENT**

Dietrich Rose/Getty Images

### **29.1 Shoot Growth and Development**

Stems grow by adding new cells at their tips.

Stem elongation occurs just below the apical meristem.

Stems branch by producing new apical meristems.

The shoot apical meristem controls the production and arrangement of leaves.

Young leaves develop vascular connections to the stem.

Flower development terminates the growth of shoot meristems.

### **29.2 Plant Hormones**

Hormones affect the growth and differentiation of plant cells.

Polar transport of auxin guides the placement of leaf primordia and the development of vascular connections with the stem.

❓ What is the developmental basis for the shorter stems of high-yielding rice and wheat?

Cytokinins, in combination with other hormones, control the outgrowth of branches.

### **29.3 Secondary Growth**

Shoots produce two types of lateral meristem.

The vascular cambium produces secondary xylem and phloem.

The cork cambium produces an outer protective layer.

Wood has both support and transport functions.

#### **29.4 Root Growth and Development**

Roots grow by producing new cells at their tips.

Root elongation and vascular development are coordinated.

The formation of new root apical meristems allows roots to branch.

The structures and functions of root systems are diverse.

#### **29.5 The Environmental Context of Growth and Development**

Plants orient the growth of their stems and roots by light and gravity.

**HOW DO WE KNOW?** How do plants grow toward light?

Seeds can delay germination if they detect the presence of plants overhead.

**HOW DO WE KNOW?** How do seeds detect the presence of plants growing overhead?

Plants grow taller and branch less when growing in the shade of other plants.

Roots elongate more and branch less when water is scarce.

Exposure to wind results in shorter and stronger stems.

## **29.6 Timing of Developmental Events**

Flowering time is affected by day length.

Plants use their internal circadian clock and photoreceptors to determine day length.

Vernalization prevents plants from flowering until winter has passed.

Plants use day length as a cue to prepare for winter.

## **CHAPTER 30 PLANT DEFENSE**

Don Johnston/Getty Images

### **30.1 Protection Against Pathogens**

Plant pathogens infect and exploit host plants by a variety of mechanisms.

Plants are able to detect and respond to pathogens.

Plants respond to infections by isolating infected regions.

Mobile signals trigger defenses in uninfected tissues.

**HOW DO WE KNOW?** Can plants develop immunity to specific pathogens?

Plants defend against viral infections by producing siRNA.

A pathogenic bacterium provides a way to modify plant genomes.

### **30.2 Defense Against Herbivores**

Plants use mechanical and chemical defenses to avoid being eaten.

Diverse chemical compounds deter herbivores.

Some plants provide food and shelter for ants, which actively defend them.

Grasses can regrow quickly following grazing by mammals.

### **30.3 Allocating Resources to Defense**

Some defenses are always present, whereas others are turned on in response to a threat.

Plants can sense and respond to herbivores.

Plants produce volatile signals that attract insects that prey upon herbivores.

Nutrient-rich environments select for plants that allocate more resources to growth than to defense.

**HOW DO WE KNOW?** Can plants communicate?

Exposure to multiple threats can lead to trade-offs.

### **30.4 Defense and Plant Diversity**

The evolution of new defenses may allow plants to diversify.

Pathogens, herbivores, and seed predators can increase plant diversity.

 Can modifying plants genetically protect crops from herbivores and pathogens?

## **CHAPTER 31 PLANT DIVERSITY**

Alfredo Maiquez/Getty Images

### **31.1 Major Themes in the Evolution of Plant Diversity**

Four major transformations in life cycle and structure characterize the evolutionary history of plants.

Plant diversity has changed over time.

### **31.2 Bryophytes**

Bryophytes are small and tough.

The small gametophytes and unbranched sporophytes of bryophytes are adaptations for reproducing on land.

Bryophytes exhibit several cases of convergent evolution with the vascular plants.

Sphagnum moss plays an important role in the global carbon cycle.

### **31.3 Spore-Dispersing Vascular Plants**

Rhynie chert fossils provide a window into the early evolution of vascular plants.

Lycophytes evolved leaves and roots independently from all other vascular plants.

Ancient lycophytes included giant trees that dominated coal swamps about 320 million years ago.

**HOW DO WE KNOW?** Did woody plants evolve more than once?

Ferns and horsetails are morphologically and

ecologically diverse.

Fern diversity has been strongly affected by the evolution of angiosperms.

### **31.4 Gymnosperms**

Seed plants have been the dominant plants on land for more than 200 million years.

Cycads and ginkgos were once both diverse and widespread.

Conifers are woody plants that thrive in dry and cold climates.

Gnetophytes are gymnosperms that have independently evolved xylem vessels and double fertilization.

### **31.5 Angiosperms**

Several innovations increased the efficiency of the angiosperm life cycle and xylem transport.

Angiosperm diversity may result in part from coevolutionary interactions with animals and other organisms.

Monocots are diverse in shape and size despite not forming a vascular cambium.

**HOW DO WE KNOW?** When did grasslands expand over the land surface?

Eudicots are the most diverse group of angiosperms.

 What can be done to protect the genetic diversity of crop species?

 **VISUAL SYNTHESIS Angiosperms: Structure and Function**

## CHAPTER 32 FUNGI

Chris Ted/Getty Images

### 32.1 Growth and Nutrition

Hyphae permit fungi to explore their environment for food resources.

Fungi transport materials within their hyphae.

Not all fungi produce hyphae.

Fungi are principal decomposers of plant tissues.

Fungi are important plant and animal pathogens.

Many fungi form symbiotic associations with plants and animals.

Lichens are symbioses between a fungus and a green alga or a cyanobacterium.

### 32.2 Reproduction

Fungi proliferate and disperse using spores.

Multicellular fruiting bodies facilitate the dispersal of sexually produced spores.

Sexual reproduction in fungi often includes a stage in which haploid cells fuse, but nuclei do not.

**HOW DO WE KNOW?** What determines the shape of fungal spores that are ejected into the air?

Genetically distinct mating types promote outcrossing.

Parasexual fungi generate genetic diversity by asexual means.

### **32.3 Diversity**

Fungi are highly diverse.

Chytrids are aquatic fungi that lack hyphae.

Zygomycetes produce hyphae undivided by septa.

Glomeromycetes form endomycorrhizae.

The Dikarya produce regular septa during mitosis.

Ascomycetes are the most diverse group of fungi.

Basidiomycetes include smuts, rusts, and mushrooms.

**HOW DO WE KNOW?** Can a fungus influence the behavior of an ant?

❓ How do fungi threaten global wheat production?

### **❓ CASE 7 Biology-Inspired Design: Using Nature to Solve Problems**

## **CHAPTER 33 ANIMAL FORM, FUNCTION, AND EVOLUTIONARY HISTORY**

### **33.1 Animal Body Plans**

What is an animal?

Animals can be classified based on type of symmetry.

Many animals have a brain and specialized sensory

organs at the front of the body.

Some animals also show segmentation.

Animals can be classified based on the number of their germ layers.

Molecular sequence comparisons have confirmed some relationships and raised new questions.

❓ Can we mimic the form and function of animals to build robots?

### **33.2 Tissues and Organs**

Most animals have four types of tissues.

Tissues are organized into organs that carry out specific functions. 7

### **33.3 Homeostasis**

Homeostasis is the active maintenance of stable conditions inside of cells and organisms.

Homeostasis is often achieved by negative feedback.

### **33.4 Evolutionary History**

Fossils and phylogeny show that animal forms were initially simple but rapidly evolved complexity.

The animal body plans we see today emerged during the Cambrian Period.

Five mass extinctions have changed the trajectory of animal evolution during the past 500 million years.

Animals began to colonize the land 420 million years ago.

Some animals show a trend toward increased body size

over time.

**HOW DO WE KNOW?** Do animals tend to get bigger over time?

## **CHAPTER 34 ANIMAL NERVOUS SYSTEMS**

Callista Images/AGE Fotostock

### **34.1 Nervous System Function and Evolution**

Animal nervous systems have three types of nerve cells.

Nervous systems range from simple to complex.

### **34.2 Neuron Structure**

Neurons share a common organization.

Neurons differ in size and shape.

Neurons are supported by other types of cells.

### **34.3 Signal Transmission**

The resting membrane potential is negative and results in part from the movement of potassium and sodium ions.

Neurons are excitable cells that transmit information by action potentials.

Neurons propagate action potentials along their axons by sequentially opening and closing adjacent Na<sup>+</sup> and K<sup>+</sup> ion channels.

**HOW DO WE KNOW?** How does electrical activity change during an action potential?

Neurons communicate at synapses.

Signals between neurons can be excitatory or inhibitory.

### **34.4 Nervous System Organization**

Nervous systems are organized into peripheral and central components.

Peripheral nervous systems have voluntary and involuntary components.

Simple reflex circuits provide rapid responses to stimuli.

### **34.5 Sensory Systems**

Sensory receptor cells detect diverse stimuli.

Sensory transduction converts a stimulus into an electrical impulse.

Chemoreceptors respond to chemical stimuli.

Mechanoreceptors detect physical forces.

❓ How do cochlear implants work?

Electromagnetic receptors sense light.

### **34.6 Brain Organization and Function**

The brain processes and integrates information received from different sensory systems.

The brain is divided into lobes with specialized functions.

Information is topographically mapped into the vertebrate cerebral cortex.

The brain allows for memory, learning, and cognition.

## **CHAPTER 35 ANIMAL MOVEMENT: MUSCLES AND**

## SKELETONS

### 35.1 How Muscles Work

Muscles use chemical energy to produce force and movement.

Muscles can be striated or smooth.

Skeletal and cardiac muscle fibers are organized into repeating contractile units called sarcomeres.

Muscles contract by the sliding of myosin and actin protein filaments.

Calcium regulates actin–myosin interaction through excitation–contraction coupling.

Calmodulin regulates calcium activation and relaxation of smooth muscle.

### 35.2 Muscle Contractile Properties

Antagonist pairs of muscles produce reciprocal motions at a joint.

**HOW DO WE KNOW?** How does actin–myosin filament overlap affect force generation in muscles?

Muscle length affects actin–myosin overlap and generation of force.

Muscle force and shortening velocity are inversely related.

Muscle force is summed by an increase in stimulation frequency and the recruitment of motor units.

Skeletal muscles have slow-twitch and fast-twitch fibers.

How do different types of muscle fibers affect the speed of animals?

### **35.3 Animal Skeletons**

Hydrostatic skeletons support animals by muscles that act on a fluid-filled cavity.

Exoskeletons provide hard external support and protection.

The rigid bones of vertebrate endoskeletons are jointed for motion and can be repaired if damaged.

### **35.4 Vertebrate Skeletons**

Vertebrate bones form directly or by forming a cartilage model first.

The two main types of bone are compact bone and spongy bone.

Bones grow in length and width, and can be repaired.

❓ Can we design smart materials to heal bones that are damaged and improve artificial joints?

Joint shape determines range of motion and skeletal muscle organization.

## **CHAPTER 36 ANIMAL ENDOCRINE SYSTEMS**

FLPA/Chris Mattison/AGE Fotostock

### **36.1 Endocrine Function**

The endocrine system helps to regulate an organism's response to its environment.

The endocrine system regulates growth and development.

**HOW DO WE KNOW?** How are growth and development controlled in insects?

The endocrine system underlies homeostasis.

### **36.2 Hormones**

Hormones act specifically on cells that bind the hormone.

Two main classes of hormones are peptide and amines, and steroid hormones.

Hormonal signals are amplified to produce a strong effect.

Hormones are evolutionarily conserved molecules with diverse functions.

### **36.3 The Vertebrate Endocrine System**

The pituitary gland integrates diverse bodily functions by secreting hormones in response to signals from the hypothalamus.

Many targets of pituitary hormones are endocrine tissues

that also secrete hormones.

Other endocrine organs have diverse functions.

The fight-or-flight response represents a change in set point in many different organs.

### **36.4 Other Forms of Chemical Communication**

Local chemical signals regulate neighboring target cells.

Pheromones are chemical compounds released into the environment that signal physiological and behavioral changes.

## **CHAPTER 37 ANIMAL CARDIOVASCULAR AND RESPIRATORY SYSTEMS**

Power and Syred/Science Source

### **37.1 Delivery of Oxygen and Elimination of Carbon Dioxide**

Diffusion governs gas exchange over short distances.

Bulk flow moves fluid over long distances.

### **37.2 Respiratory Gas Exchange**

Many aquatic animals breathe through gills.

Insects breathe air through tracheae.

Most terrestrial vertebrates breathe by tidal ventilation of internal lungs.

Mammalian lungs are well adapted for gas exchange.

The structure of bird lungs allows unidirectional airflow for increased oxygen uptake.

Voluntary and involuntary mechanisms control breathing.

### **37.3 Oxygen Transport by Hemoglobin**

Blood is composed of fluid and several types of cell.

Hemoglobin is an ancient molecule with diverse roles related to oxygen binding and transport.

Hemoglobin reversibly binds oxygen.

**HOW DO WE KNOW?** What is the molecular structure of hemoglobin and myoglobin?

Myoglobin stores oxygen, enhancing oxygen delivery to muscle mitochondria.

Many factors affect hemoglobin–oxygen binding.

### **37.4 Circulatory Systems**

Circulatory systems have vessels of different sizes.

Arteries are muscular vessels that carry blood away from the heart under high pressure.

Veins are thin-walled vessels that return blood to the heart under low pressure.

Compounds and fluid move across capillary walls by diffusion, filtration, and osmosis.

Hormones and nerves provide homeostatic regulation of blood pressure.

### **37.5 Structure and Function of the Heart**

Fishes have two-chambered hearts and a single

circulatory system.

Amphibians and reptiles have three-chambered hearts and partially divided circulations.

Mammals and birds have four-chambered hearts and fully divided pulmonary and systemic circulations.

❓ How can we engineer replacement heart valves?

Cardiac muscle cells are electrically connected to contract in synchrony.

Heart rate and cardiac output are regulated by the autonomic nervous system.

## **CHAPTER 38 ANIMAL METABOLISM, NUTRITION, AND DIGESTION**

Thomas Kokta/Getty Images

### **38.1 Patterns of Animal Metabolism**

Animals rely on anaerobic and aerobic metabolism.

Metabolic rate varies with activity level.

Metabolic rate is affected by body size.

Metabolic rate is linked to body temperature.

**HOW DO WE KNOW?** How is metabolic rate affected by running speed and body size?

**VS VISUAL SYNTHESIS Homeostasis and Thermoregulation**

### **38.2 Nutrition and Diet**

Energy balance is a form of homeostasis.

An animal's diet must supply nutrients that it cannot synthesize.

### **38.3 Adaptations for Feeding**

Suspension filter feeding is common in many aquatic animals.

Large aquatic animals apprehend prey by suction feeding and active swimming.

Specialized structures allow for capture and mechanical breakdown of food.

### **38.4 Regional Specialization of the Gut**

Most animal digestive tracts have three main parts: a foregut, midgut, and hindgut.

Digestion begins in the mouth.

Further digestion and storage of nutrients take place in the stomach.

Final digestion and nutrient absorption take place in the small intestine.

The large intestine absorbs water and stores waste.

The lining of the digestive tract is composed of distinct layers.

Plant-eating animals have specialized digestive tracts adapted to their diets.

## **CHAPTER 39 ANIMAL RENAL SYSTEMS: WATER AND WASTE**

Steve Allen/Getty Images

### **39.1 Water and Electrolyte Balance**

Osmosis governs the movement of water across cell membranes.

Osmoregulation is the control of osmotic pressure inside cells and organisms.

Osmoconformers match their internal solute concentration to that of the environment.

Osmoregulators have internal solute concentrations that differ from that of their environment.

### **39.2 Excretion of Wastes**

The excretion of nitrogenous wastes is linked to an animal's habitat and evolutionary history.

Excretory organs work by filtration, reabsorption and secretion.

Animals have diverse excretory organs.

Vertebrates filter blood under pressure through paired kidneys.

### **39.3 The Mammalian Kidney**

The mammalian kidney has an outer cortex and inner medulla.

Glomerular filtration isolates wastes carried by the blood along with water and small solutes.

The proximal convoluted tubule reabsorbs solutes by active transport.

The loop of Henle acts as a countercurrent multiplier to create a concentration gradient from the cortex to the medulla.

**HOW DO WE KNOW?** How does the mammalian kidney produce concentrated urine?

The distal convoluted tubule secretes additional wastes.

The final concentration of urine is determined in the collecting ducts and is under hormonal control.

The kidneys help regulate blood pressure and blood volume.

❓ How does dialysis work?

## **CHAPTER 40 ANIMAL REPRODUCTION AND DEVELOPMENT**

SPL/Science Source

### **40.1 The Evolutionary History of Reproduction**

Asexual reproduction produces clones.

Sexual reproduction involves the formation and fusion of gametes.

Many species reproduce both sexually and asexually.

Exclusive asexuality is often an evolutionary dead end.

**HOW DO WE KNOW?** Do bdelloid rotifers only reproduce asexually?

#### **40.2 Movement onto Land and Reproductive Adaptations**

Fertilization can take place externally or internally.  
*r*-strategists and *K*-strategists differ in number of offspring and parental care.

Animals either lay eggs or give birth to live young.

#### **40.3 Human Reproductive Anatomy and Physiology**

The male reproductive system is specialized for the production and delivery of sperm.

The female reproductive system produces eggs and supports the developing embryo.

Hormones regulate the human reproductive system.

#### **40.4 Gamete Formation to Birth in Humans**

Male and female gametogenesis have both shared and distinct features.

Fertilization occurs when a sperm fuses with an oocyte.

The first trimester includes cleavage, gastrulation, and organogenesis.

The second and third trimesters are characterized by fetal growth.

Childbirth is initiated by hormonal changes.

**VISUAL SYNTHESIS Reproduction and Development**

### **CHAPTER 41 ANIMAL IMMUNE SYSTEMS**

SPL/Science Source

## **41.1 An Overview of the Immune System**

Pathogens cause disease.

The immune system distinguishes self from nonself.

The immune system consists of innate and adaptive immunity.

## **41.2 Innate Immunity**

The skin and mucous membranes provide the first line of defense against infection.

White blood cells provide a second line of defense against pathogens.

Phagocytes recognize foreign molecules and send signals to other cells.

Inflammation is a coordinated response to tissue injury.

The complement system participates in the innate and adaptive immune systems.

❓ How can we use a protein that circulates in the blood to treat sepsis?

## **41.3 B Cells and Antibodies**

B cells produce antibodies.

Mammals produce five classes of antibodies with different functions.

Clonal selection is the basis for antibody specificity.

Clonal selection explains immunological memory.

**HOW DO WE KNOW?** How is antibody diversity generated?

Genomic rearrangement generates antibody diversity.

#### **41.4 T Cells and Cell-Mediated Immunity**

T cells include helper and cytotoxic cells.

T cells have T cell receptors on their surface that recognize an antigen in association with MHC proteins.

The ability to distinguish between self and nonself is acquired during T cell maturation.

#### **41.5 Three Pathogens**

The flu virus evades the immune system by antigenic drift and shift.

Tuberculosis is caused by a slow-growing, intracellular bacterium.

The malaria parasite changes surface molecules by antigenic variation.

### **CHAPTER 42 ANIMAL DIVERSITY**

Brian Farrell

#### **42.1 Sponges, Cnidarians, Ctenophores, and Placozoans**

Sponges share some features with choanoflagellates but also exhibit adaptations conferred by multicellularity.

Cnidarians are the architects of life's largest constructions: coral reefs.

Ctenophores and placozoans represent the extremes of body organization among phyla that branch from early nodes on the animal tree.

Branching relationships among early nodes on the animal tree remain uncertain.

#### **42.2 Protostome Animals**

Lophotrochozoans account for nearly half of all animal phyla, including the diverse and ecologically important annelids and mollusks.

Ecdysozoans are animals that episodically molt their external cuticle during growth.

#### **42.3 Arthropods**

The Arthropoda is the most diverse animal phylum.

**HOW DO WE KNOW?** How did the diverse feeding structures of arthropods arise?

Insects make up the majority of all known animal species and have adaptations that allow them to live in diverse habitats.

#### **42.4 Deuterostome Animals**

Hemichordates include acorn worms and pterobranchs, and echinoderms include sea stars and sea urchins.

Chordates include vertebrates, cephalochordates, and tunicates.

#### **42.5 Vertebrates**

Fish are the most diverse vertebrate animals.

The common ancestor of tetrapods had four limbs.

Amniotes evolved terrestrial eggs.

## CHAPTER 43 BEHAVIOR AND BEHAVIORAL ECOLOGY

Dan L. Perlman/EcoLibrary.org

### 43.1 Tinbergen's Questions

Tinbergen asked proximate and ultimate questions about behavior.

### 43.2 Dissecting Behavior

The fixed action pattern is a stereotyped behavior.

The nervous system processes stimuli and evokes behaviors.

Hormones can trigger certain behaviors.

Breeding experiments can help determine the degree to which a behavior is genetic.

Molecular techniques provide new ways of testing the role of genes in behavior.

HOW DO WE KNOW? Can the same gene influence

behavior differently in different species?

### **43.3 Learning**

Non-associative learning occurs without linking two events.

Associative learning occurs when two events are linked.

**HOW DO WE KNOW?** To what extent are insects capable of learning?

Learning is an adaptation.

### **43.4 Information Processing**

Orientation involves a directed response to a stimulus.

Navigation is demonstrated by the remarkable ability of homing in birds.

Biological clocks provide important time cues for many behaviors.

**HOW DO WE KNOW?** Does a biological clock play a role in birds' ability to orient?

### **43.5 Communication**

Communication is the transfer of information between a sender and a receiver.

Some forms of communication are complex and learned during a sensitive period.

Various forms of communication can convey specific information.

### **43.6 Social Behavior**

Group selection is a weak explanation of altruistic behavior.

Reciprocal altruism is one way that altruism can evolve.

Kin selection is based on the idea that it is possible to contribute genetically to future generations by helping close relatives.

## **CHAPTER 44 POPULATION ECOLOGY**

Eladio M. Fernandez

### **44.1 Populations and Their Properties**

A population includes all the individuals of a species in a particular place.

Three key features of a population are its size, range, and density.

Ecologists estimate population size by sampling.

**HOW DO WE KNOW?** How many butterflies are there in a given population?

### **44.2 Population Growth and Decline**

Population size is affected by birth, death, immigration, and emigration.

Population size increases rapidly when the per capita growth rate is constant over time.

Carrying capacity is the maximum number of individuals a habitat can support.

Logistic growth produces an S-shaped curve and

describes the growth of many natural populations.

Factors that influence population growth can be dependent on or independent of population density.

### **44.3 Age-Structured Population Growth**

Birth and death rates vary with age and environment.

Survivorship curves record changes in survival probability over an organism's life-span.

Patterns of survivorship vary among organisms.

Reproductive patterns reflect the predictability of a species' environment.

The life history of an organism shows trade-offs among physiological functions.

### **44.4 Metapopulation Dynamics**

A metapopulation is a group of populations linked by immigrants.

❓ How do populations colonize islands?

## **CHAPTER 45 SPECIES INTERACTIONS AND COMMUNITIES**

Charles J. Smith

### **45.1 The Niche**

The niche is a species' place in nature.

The realized niche of a species is more restricted than its

fundamental niche.

Niches are shaped by evolutionary history.

## **45.2 Antagonistic Interactions**

Limited resources foster competition.

Species compete for resources other than food.

Competitive exclusion prevents two species from occupying the same niche at the same time.

❓ Can competition drive species diversification?

Predation, parasitism, and herbivory are interactions in which one species benefits at the expense of another.

**HOW DO WE KNOW?** Can predators and prey coexist stably in certain environments?

## **45.3 Mutualistic Interactions**

Mutualisms are interactions between species that benefit both participants.

Mutualisms may evolve increasing interdependence.

Digestive symbioses recycle plant material.

**HOW DO WE KNOW?** Have aphids and their symbiotic bacteria coevolved?

Mutualisms may be obligate or facultative.

In some interactions, one partner is unaffected by the interaction.

Facilitation occurs when one species indirectly benefits another.

The costs and benefits of species interactions can change over time.

## 45.4 Communities

Species that live in the same place make up communities.

❓ How is biodiversity measured?

Species influence each other in a complex web of interactions.

Keystone species have disproportionate effects on communities.

Disturbance can modify community composition.

Succession describes the community response to new habitats or disturbance.

Island biogeography explains species diversity on habitat islands.

 VISUAL SYNTHESIS Succession: Ecology in Microcosm

## CHAPTER 46 ECOSYSTEM ECOLOGY

Andre Gallant/Getty Images

### 46.1 The Short-Term Carbon Cycle

The Keeling curve records changing levels of carbon dioxide in the atmosphere over time.

Photosynthesis and respiration are key processes in short-term carbon cycling.

The regular oscillation of CO<sub>2</sub> reflects the seasonality of photosynthesis in the Northern Hemisphere.

Human activities play an important role in the modern carbon cycle.

**HOW DO WE KNOW?** How much CO<sub>2</sub> was in the atmosphere 1000 years ago?

Carbon isotopes show that much of the CO<sub>2</sub> added to air over the past half century comes from burning fossil fuels.

**HOW DO WE KNOW?** What is the major source of the CO<sub>2</sub> that has accumulated in Earth's atmosphere over the past two centuries?

#### **46.2 The Long-Term Carbon Cycle**

Records of atmospheric composition over 400,000 years show periodic shifts in CO<sub>2</sub> levels.

Reservoirs and fluxes are key in long-term carbon cycling.

#### **46.3 Food Webs and Trophic Pyramids**

Food webs trace carbon and other elements through communities and ecosystems.

Energy as well as carbon is transferred through ecosystems.

#### **46.4 Other Biogeochemical Cycles**

The nitrogen cycle is closely linked to the carbon cycle.

Phosphorus cycles through ecosystems, supporting primary production.

## 46.5 The Ecological Framework of Biodiversity

Biological diversity reflects the many ways that organisms participate in biogeochemical cycles.

Biological diversity can influence primary production and therefore the biological carbon cycle.

Biogeochemical cycles weave together biological evolution and environmental change through Earth history.

HOW DO WE KNOW? Does species diversity promote primary productivity?

 VISUAL SYNTHESIS Flow of Matter and Energy Through Ecosystems

## CHAPTER 47 CLIMATE AND BIOMES

Mike Hill/Getty Images

### 47.1 Climate

The principal control on Earth's surface temperature is the angle at which solar radiation strikes the surface.

Heat is transported toward the poles by wind and ocean currents.

Global circulation patterns determine patterns of rainfall, but topography also matters.

### 47.2 Biomes

Terrestrial biomes reflect the distribution of climate.

Aquatic biomes reflect climate, the availability of nutrients and oxygen, and the depth to which sunlight penetrates through water.

Marine biomes cover most of our planet's surface.

### **47.3 Global Patterns**

Global patterns of primary production reflect variations in climate and nutrient availability.

**HOW DO WE KNOW?** Does iron limit primary production in some parts of the oceans?

Biodiversity is highest at the equator and lowest toward the poles.

**?** How do evolutionary and ecological history explain biodiversity?

## **CHAPTER 48 THE ANTHROPOCENE: HUMANS AS A PLANETARY FORCE**

Michael Utech/Getty Images

### **48.1 The Anthropocene Epoch**

Humans are a major force on the planet.

### **48.2 Human Influence on the Carbon Cycle**

As atmospheric carbon dioxide levels have increased, so has mean surface temperature.

Changing environments affect species distribution and community composition.

❓ How has global environmental change affected coral reefs around the world?

What can be done?

**HOW DO WE KNOW?** How will rising twenty-first-century CO<sub>2</sub> levels affect coral reefs?

### **48.3 Human Influence on the Nitrogen and Phosphorus Cycles**

Nitrogen fertilizer transported to lakes and the sea causes eutrophication.

Phosphate fertilizer is also used in agriculture, but has finite sources.

What can be done?

### **48.4 Human Influence on Evolution**

Human activities have reduced the quality and size of many habitats, decreasing the number of species they can support.

Overexploitation threatens species and disrupts ecological relationships within communities.

Humans play an important role in the dispersal of species.

Humans have altered the selective landscape for many pathogens.

Are amphibians ecology's "canary in the coal mine"?

### **48.5 Conservation Biology**

 What are our conservation priorities?

Conservation biologists have a diverse toolkit for confronting threats to biodiversity.

Climate change provides new challenges for conservation biology in the twenty-first century.

Sustainable development provides a strategy for conserving biodiversity while meeting the needs of the human population.

**48.6 Scientists and Citizens in the Twenty-First Century**

## HOW LIFE WORKS

# PART 1 FROM CELLS TO ORGANISMS

Davidcallan/Getty Images

“Nothing in biology makes sense except in the light of evolution.”

—THEODOSIUS DOBZHANSKY

# CHAPTER 1 Life Chemical, Cellular, and Evolutionary Foundations

Ralph Lee Hopkins/Getty Images

---

## CORE CONCEPTS

**1.1 SCIENTIFIC INQUIRY:** Scientific inquiry is a deliberate way of

asking and answering questions about the natural world.

**1.2 CHEMICAL AND PHYSICAL PROPERTIES:** Life works according to fundamental principles of chemistry and physics.

**1.3 THE CELL:** The fundamental unit of life is the cell.

**1.4 EVOLUTION:** Evolution explains the features that organisms share and those that set them apart.

**1.5 ECOLOGICAL SYSTEMS:** Organisms interact with one another and with their physical environment, shaping ecological systems that sustain life.

**1.6 THE HUMAN FOOTPRINT:** In the twenty-first century, humans have become major agents in ecology and evolution.

---

Every day, remarkable things happen within and around you. Strolling through a local market, you come across a bin full of crisp apples, pick one up, and take a bite. Underlying this unremarkable occurrence is an extraordinary series of events. Your eyes sense the apple from a distance, and nerves carry that information to your brain, permitting identification. Biologists call this cognition, an area of biological study. Stimulated by the apple and recognizing it as ripe and tasty, your brain transmits impulses through nerves to your muscles. How we respond to external cues motivates behavior, another biological discipline. Grabbing the apple requires the coordinated activities of dozens of muscles that move your arm and hand to a precise spot. These movements are described by biomechanics, yet another area of biological research. And, as you bite down on the apple, glands in your mouth secrete saliva, starting to convert energy stored in the apple as

sugar into energy that you will use to fuel your own activities. Physiology, like biomechanics, lies at the heart of biological function.

Studies of cognition, behavior, biomechanics, and physiology are all ways of approaching **biology**, the science of how life works.

**Biologists**, scientists who study life, have come to understand a great deal about these and other processes at levels that run the gamut from molecular mechanisms within the cell, through the integrated actions of many cells within an organ or body, to the interactions among different organisms in nature. We don't know everything about how life works—in fact, it seems as if every discovery raises new questions. But biology provides us with an organized way of understanding ourselves and the world around us.

Why study biology? The example of eating an apple was deliberately chosen because it is an everyday occurrence that we ordinarily wouldn't think about twice. The scope of modern biology, however, is vast, raising questions that can fire our imaginations, affect our health, and influence our future. How, for example, will our understanding of the human genome change the way that we fight cancer? How do bacteria in our digestive system help determine health and well-being? Will expected changes in the temperature and pH of seawater doom coral reefs? Is there, or has there ever been, life on Mars? And, to echo the great storyteller Rudyard Kipling, why do leopards have spots, and tigers stripes?

We can describe six grand themes that connect and unite the many dimensions of life science, from molecules to the biosphere. These six

themes are stated as Core Concepts for this chapter and are introduced in the following sections. Throughout the book, these themes will be visited again and again. We view them as the keys to understanding the many details in subsequent chapters and relating them to one another. Our hope is that by the time you finish this book, you will have an understanding of how life works, from the molecular machines inside cells and the metabolic pathways that cycle carbon through the biosphere to the process of evolution, which has shaped the living world that surrounds (and includes) us. You will, we hope, see the connections among these different ways of understanding life, and come away with a greater understanding of how scientists think about and ask questions about the natural world. How, in fact, do we know what we think we know about life? We also hope you will develop a basis for making informed decisions about your life, career, and the actions you take as a citizen.

# 1.1 SCIENTIFIC INQUIRY

How do we go about trying to understand the vastness and complexity of nature? For most scientists, studies of the natural world involve the complementary processes of observation and experimentation.

**Observation** is the act of viewing the world around us.

**Experimentation** is a disciplined and controlled way of asking and answering questions about the world in an unbiased manner.

Observation allows us to draw tentative explanations called hypotheses.

Observations allow us to ask focused questions about nature. Let's say you observe a hummingbird like the one pictured in **Fig. 1.1** hovering near a red flower, occasionally dipping its long beak into the bloom. What motivates this behavior? Is the bird feeding on some substance within the flower? Is it drawn to the flower by its vivid color? What benefit, if any, does the flower derive from this busy bird?

Source: Charles J. Smith.

FIG. 1.1 A hummingbird visiting a flower. This simple observation leads to questions: why do hummingbirds pay so much attention to some flowers? Why do they hover near red flowers?

Observations such as these, and the questions they raise, allow us to propose tentative explanations, or [hypotheses](#). We might, for example, hypothesize that the hummingbird is carrying pollen from one flower to the next, facilitating reproduction in the plant. Or we might hypothesize that nectar produced deep within the flower provides nutrition for the hummingbird—that the hummingbird's actions reflect its need to take in food. Both hypotheses provide a reasonable explanation of the behavior we observed, but they may or may not be correct. To find out, we have to test them.

Charles Darwin's classic book, *On the Origin of Species*, published in 1859, beautifully illustrates how we can piece together individual

observations to construct a working hypothesis. In this book, Darwin discussed a wide range of observations, from pigeon breeding to fossils and from embryology to the unusual animals and plants found on islands. Darwin noted the success of animal breeders in selecting specific individuals for reproduction, thereby generating new breeds for agriculture or show. He appreciated that selective breeding is successful only if specific features of the animals can be passed from one generation to the next by inheritance. Reading economic treatises by the English clergyman Thomas Malthus, he understood that limiting environmental resources could select among the different individuals in populations in much the way that breeders select among cows or pigeons.

Gathering together all these seemingly disparate pieces of information, Darwin argued that life has evolved over time by means of natural selection. Since its formulation, Darwin's initial hypothesis has been tested by experiments, many thousands of them. Our knowledge of many biological phenomena, ranging from biodiversity to the way the human brain is wired, depends on direct observation followed by careful inferences that lead to models of how things work.

## A hypothesis makes predictions that can be tested by observation and experiments.

Not just any idea qualifies as a hypothesis. Two features set hypotheses apart from other ways of attacking problems. First, a good hypothesis makes predictions about observations not yet made or experiments not

yet run. Second, because hypotheses make predictions, we can test them. That is, we can devise an experiment to see whether the predictions made by the hypothesis actually occur, or we can go into the field to try to make further observations predicted by the hypothesis. A hypothesis, then, is a statement about nature that can be tested by experiments or by new observations. Hypotheses are testable because, even as they suggest an explanation for observations made previously, they make predictions about observations yet to be made.

Once we have a hypothesis, we can test it to see if its predictions are accurate (**Fig. 1.2**). Returning to the hummingbird and flower, we can test the hypothesis that the bird is transporting pollen from one flower to the next, enabling the plant to reproduce. Observation provides one type of test: if we catch and examine the bird just after it visits a flower, do we find pollen stuck to its beak or feathers? If so, our hypothesis survives the test.

FIG. 1.2 Scientific inquiry.

Note, however, that we haven't proved the case. Pollen might be stuck on the bird for a different reason—perhaps it provides food for the hummingbird. However, if the birds *didn't* carry pollen from flower to flower, we would reject the hypothesis that they facilitate pollination. In other words, a single observation or experiment can lead us to reject a hypothesis, or it can support the hypothesis, but it cannot prove that a hypothesis is correct. To move forward, then, we might make a second set of observations. Does pollen that adheres to the hummingbird rub off when the bird visits a second flower of the same species? If so, we have stronger support for our hypothesis.

We might also use observations to test a more general hypothesis about birds and flowers. Does red color generally attract birds and so facilitate pollination in a wide range of flowers? To answer this question, we might catalog the pollination of many red flowers and ask whether they are pollinated mainly by birds. Or we might go the opposite direction and catalog the flowers visited by many different birds—are they more likely to be red than chance alone might predict?

Finally, we can test the hypothesis that the birds visit the flowers primarily to obtain food, spreading pollen as a side effect of their feeding behavior. We can measure the amount of nectar in the flower before and after the bird visits and calculate how much energy has been consumed by the bird during its visit. Continued observations over the course of the day will tell us whether the birds gain the nutrition they need by drinking nectar, and whether the birds have other sources of food.

In addition to observations, in many cases we can design experiments to test hypotheses ([Fig. 1.2](#)). One of the most powerful types of experiment is called a controlled experiment. In a controlled experiment, the researcher sets up several groups to be tested, keeping the conditions and setup as similar as possible from one group to the next. Then, the researcher deliberately introduces something different, known as a [variable](#), into one group that he or she hypothesizes might have some sort of an effect. This is called the [test group](#). In another group, the researcher does not introduce this variable. This is a [control group](#), and the expectation is that no effect will occur in this group.

Controlled experiments are extremely powerful. By changing just one variable at a time, the researcher is able to determine whether that variable is important. If many variables were changed at once, it would be difficult, if not impossible, to draw conclusions from the experiment because the researcher would not be able to figure out which variable caused the outcome. The control group plays a key role as well. Having a group in which no change is expected ensures that the experiment works as it is supposed to and provides a baseline against which to compare the results of the test groups.

For example, we might test the hypothesis that hummingbirds facilitate pollination by doing a controlled experiment. In this case, we could set up groups of red flowers that are all similar to one another. For one group, we could surround the flowers with a fine mesh that allows small insects access to the plant but keeps hummingbirds away. For another group, we would not use a mesh. The variable, then, is the presence of a mesh; the test group is the flowers with the mesh; and the

control group is the flowers without the mesh since the variable was not introduced in this group.

Will the flowers be pollinated? If only the group without the mesh is pollinated, this result lends support to our initial hypothesis. In this case, the hypothesis becomes less tentative and more certain. If both groups are pollinated, our hypothesis is not supported, in which case we may discard it for another explanation or change it to account for the new information.

Using observations to generate a hypothesis and then making predictions based on that hypothesis are two steps in what is sometimes called the scientific method. In reality, however, there is no single pathway to new knowledge about the world. To convey the full range of activities by which science works, we instead use the term **scientific inquiry** to describe the process outlined in [Fig. 1.2](#). Scientific inquiry encompasses several careful and deliberate ways of asking and answering questions about the unknown. We ask questions, make observations, collect field or laboratory samples, and design and carry out experiments or analyses to make sense of things we initially do not understand. We then communicate what we find with other scientists and the public. Discussing and sharing ideas and results often lead to new questions, which in turn can be tested by observations and experiments. Scientific inquiry has been spectacularly successful in helping us to understand the world around us. We explore several aspects of scientific inquiry, including skills that scientists use to ask and answer questions, in your online courseware.

To emphasize the power of scientific inquiry, we turn to a famous riddle drawn from the fossil record ([Fig. 1.3](#)). Since the nineteenth century, paleontologists have known that before mammals expanded to their current ecological importance, other large animals dominated Earth. Dinosaurs evolved about 240 million years ago and disappeared abruptly 66 million years ago, along with many other species of plants, animals, and microscopic organisms. Because in many cases the skeletons and shells of these creatures were buried in sediment and became fossilized, we can read a record of their evolutionary history from layers of sedimentary rock deposited one atop another.

#### HOW DO WE KNOW?

### FIG. 1.3

## What caused the extinction of the dinosaurs?

#### BACKGROUND

Dinosaurs dominated the Earth for nearly 150 million years but became extinct about 66 million years ago.

#### OBSERVATION

#### HYPOTHESIS

Geologist Walter Alvarez and his colleagues hypothesized that a large meteorite struck the Earth, disrupting communities on land and in the sea

and causing the extinction of the dinosaurs and many other species.

### PREDICTIONS

A hypothesis makes predictions that can be tested by observation and experiments. To support the hypothesis, independent evidence of a meteor impact should be found in rock layers corresponding to the time of the extinction and be rare or absent in older and younger layers.

### FURTHER OBSERVATIONS

### CONCLUSION

A giant meteor struck the Earth 66 million years ago, causing the extinction of many species, including the dinosaurs.

### FOLLOW-UP WORK

Researchers have documented other mass extinctions, but the event that eliminated the dinosaurs appears to be the only one associated with a meteorite impact.

SOURCE Alvarez, W. 1998. *T. rex and the Crater of Doom*. New York: Vintage Press.

Working in Italy, the American geologist Walter Alvarez collected

samples from the precise point in the rock layers that corresponds to the time of the extinction. Careful chemical analysis showed that rocks at this level are unusually enriched in the element iridium. Iridium is rare in most rocks on continents and the seafloor, but is relatively common in rocks that fall from space—that is, in meteorites. From these observations, Alvarez and his colleagues developed a remarkable hypothesis: 66 million years ago, a large meteor slammed into Earth, and in the resulting environmental havoc, dinosaurs and many other species became extinct. This hypothesis makes specific predictions, described in [Fig. 1.3](#), which turn out to be supported by further observations.

## A theory is a general explanation of natural phenomena supported by many experiments and observations.

As already noted, a hypothesis may initially be tentative. Indeed, it often provides only one of several possible ways of explaining existing data. With repeated observation and experimentation, however, a good hypothesis gathers strength, and we have more and more confidence in it. When a number of related hypotheses survive repeated testing and come to be accepted as good bases for explaining what we see in nature, scientists articulate a broader explanation that accounts for all the hypotheses and the results of their tests. We call this statement a [theory](#), a general explanation of the world supported by a large body of experiments and observations (see [Fig. 1.2](#)).

Note that scientists use the word “theory” in a very particular way.

In general conversation, “theory” is often synonymous with “hypothesis,” “idea,” or “hunch”—“I’ve got a theory about that.” But in a scientific context, the word “theory” has a specific meaning. Scientists speak in terms of theories only if hypotheses have withstood testing to the point where they provide a general explanation for many observations and experimental results. Just as a good hypothesis makes testable predictions, a good theory both generates good hypotheses and predicts their outcomes. Thus, scientists talk about the theory of gravity—a set of hypotheses you test every day by walking down the street or dropping a fork. Similarly, the theory of evolution is not one explanation among many for the unity and diversity of life. Instead, it is a set of hypotheses that has been tested for more than a century and shown to provide an extraordinarily powerful explanation of biological observations that range from the amino acid sequences of proteins to the diversity of ants in a rain forest. In fact, as we discuss throughout this book, evolution is the single most important theory in all of biology. It provides the most general and powerful explanation of how life works.

#### Self-Assessment Questions

1. How does a scientist turn an observation into a hypothesis and investigate that hypothesis?
2. What are the differences among a guess, hypothesis, and theory?
3. Mice that live in sand dunes commonly have light tan fur. Develop a hypothesis to explain this coloration.
4. What are the differences between a test group and a control

group, and why is it important for an experiment to have both types of groups?

5. Design a controlled experiment to test the hypothesis that cigarette smoke causes lung cancer.

## 1.2 CHEMICAL AND PHYSICAL PRINCIPLES

We stated earlier that biology is the study of life. But what exactly *is* life? As simple as this question seems, it is frustratingly difficult to answer. We all recognize life when we see it, but coming up with a definition is harder than it first appears.

Living organisms are clearly different from nonliving things. But just how different is an organism from the rock shown in [Fig. 1.4](#)? On one level, the comparison is easy: the rock is much simpler than any living organism we can think of. It has far fewer components, and it is largely static, with no apparent response to environmental change on timescales that are readily tracked.

Source: Scott Hailstone/Getty Images.

FIG. 1.4 A climber scaling a rock. Living organisms like this climber contain chemicals that are found in rocks, but only living organisms reproduce in a manner that allows for evolution over time.

In contrast, even an organism as relatively simple as a bacterium contains many hundreds of different chemical compounds organized in a complex manner. The bacterium is also dynamic in that it changes continuously, especially in response to the environment. Unlike rocks and minerals, organisms metabolize—that is, they take in energy and materials from their environment and use those resources to grow and do work. Organisms reproduce, but minerals do not. And organisms do something else that rocks and minerals don't: they evolve. Indeed, the molecular biologist Gerald Joyce has defined life as a chemical system capable of undergoing Darwinian evolution.

From these simple comparisons, we can highlight key characteristics of living organisms: complexity, with precise spatial organization on several scales; the ability to change in response to the environment; the abilities to metabolize and to reproduce; and the capacity to evolve. Nevertheless, the living and nonliving worlds share an important attribute: both are subject to the laws of chemistry and physics.

**The living and nonliving worlds follow the same chemical rules and obey the same physical laws.**

The chemical elements found in rocks and other nonliving things are

no different from those found in living organisms. In other words, all the elements that make up living things can be found in the nonliving environment—there is nothing special about our chemical components when taken individually. That said, the *relative* abundances of elements in organisms differ greatly from those in the nonliving world. In the universe as a whole, hydrogen and helium make up more than 99% of known matter, while Earth's crust contains mostly oxygen and silicon, with significant amounts of aluminum, iron, and calcium ([Fig. 1.5a](#)). In organisms, by contrast, oxygen, carbon, and hydrogen are by far the most abundant elements ([Fig. 1.5b](#)). As discussed more fully in [Chapter 2](#), carbon provides the chemical backbone of life. The particular properties of carbon make possible a wide diversity of molecules that, in turn, support a wide range of functions within cells.

**a. Earth's crust**

Earth's crust consists mainly of oxygen and silicon.

**b. Human body**

Cells in the human body are made up mostly of oxygen, carbon, and hydrogen.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

**FIG. 1.5** Composition by mass of (a) Earth's crust and (b) cells in the human body. The Earth beneath our feet is made up of the same elements found in our feet, but in strikingly different proportions.

All living organisms are subject to the physical laws of the universe. Physics helps us to understand how animals move and why trees don't fall over; it explains how redwoods conduct water upward through their trunks and how oxygen gets into the cells that line your lungs. Indeed, two laws of thermodynamics, both of which describe how energy is transformed in any system, determine how living organisms are able to do work and maintain their spatial organization.

The **first law of thermodynamics** states that energy can neither be created nor destroyed; it can only be transformed from one form into another. In other words, the total energy in the universe is constant, but the form that energy takes can change. Living organisms are energy transformers. They acquire energy from the environment and transform it into a chemical form that cells can use. All organisms obtain energy from the sun or from chemical compounds. Some of this energy is used to do work—such as moving, reproducing, and building cellular components—and the rest is dissipated as heat. The energy that is used to do work plus the heat that is generated is the total amount of energy, which is the same as the input energy (**Fig. 1.6**). In other words, the total amount of energy remains constant before and after energy transformation.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 1.6 Energy transformation and the first law of thermodynamics. The first law states that the total amount of energy in any system remains the same. Organisms transform energy from one form to another, but the total energy in any system is constant.

The **second law of thermodynamics** states that the degree of disorder (or the number of possible positions and motions of molecules) in the universe tends to increase. Think about a box full of marbles distributed more or less randomly; if you want to line up all the red ones or blue ones in a row, you have to do work—that is, you have to add energy. In this case, the addition of energy increases the order of the system, or, put another way, decreases its disorder. Physicists quantify the amount of disorder (or the number of possible positions and motions of molecules) in a system as the **entropy** of the system.

Living organisms are highly organized. As with lining up marbles in

a row, energy is needed to maintain this organization. Given the tendency toward greater disorder, the high level of organization of even a single cell would appear to violate the second law. But it does not. The key is that a cell is not an isolated system and therefore cannot be considered on its own; it exists in an environment. So we need to take into account the whole system, the cell plus the environment that surrounds it. Only some of the energy harnessed by cells is used to do work; the rest is dissipated as heat ([Fig. 1.6](#)). That is, conversion of energy from one form to another is never 100% efficient. Heat is a form of energy, so the total amount of energy is conserved, as dictated by the first law. In addition, heat corresponds to the motion of small molecules—the greater the heat, the greater the motion, and the greater the motion, the greater the degree of disorder. Therefore, the release of heat as organisms harness energy means that the total entropy for the combination of the cell and its surroundings increases, in keeping with the second law ([Fig. 1.7](#)).

## Scientific inquiry shows that living organisms come from other living organisms.

Life is made up of chemical components that also occur in the nonliving environment and obey the same laws of chemistry and

physics. Can life spontaneously arise from these nonliving materials? We all know that living organisms come from other living organisms, but it is worth asking *how* we know this. Direct observation can be misleading here. For example, raw meat, if left out on a plate, will rot and become infested with maggots (fly larvae). It might seem as though the maggots appear spontaneously. In fact, the question of where maggots come from was a matter of vigorous debate for centuries. In the 1600s, the Italian physician and naturalist Francesco Redi conducted an experiment to test the hypothesis that maggots (and hence flies) in rotting meat come from other flies that laid their eggs in the meat. He found that living organisms come from other organisms and do not appear spontaneously ([Fig. 1.8](#)).

#### HOW DO WE KNOW?

### FIG. 1.8

## Can living organisms arise from nonliving matter?

#### BACKGROUND

Until the 1600s, many people believed that rotting meat spontaneously generates maggots (fly larvae).

#### HYPOTHESIS

Francesco Redi hypothesized that maggots come from flies and are not spontaneously generated.

#### EXPERIMENT

Redi placed meat in three jars. He left one jar open; he covered one with gauze; and he sealed one with a cap. The three jars were subject to the same conditions—the only variable was the opening. The open jar allowed for the passage of flies and air; the jar with the gauze allowed for the

passage of air but not flies; and the sealed jar did not allow the passage of air or flies.

### RESULTS

Redi observed that maggots appeared only on the meat in the open jar. No maggots appeared in the other two jars, which did not allow access to the meat by flies.

### CONCLUSION

The presence of maggots in the open jar and the absence of maggots in the gauze-covered and sealed jars supported the hypothesis that maggots come from flies.

### FOLLOW-UP WORK

Redi's experiment argued against the idea of spontaneous generation for insects. However, it was unclear whether his results could be extended to microbes. Applying the scientific process, Louis Pasteur used a similar approach about 200 years later to investigate this question ([Fig. 1.9](#)).

Some argued, however, that Redi's results might only apply to larger organisms; microscopic life might be another matter entirely. In

the nineteenth century, the French chemist and biologist Louis Pasteur conducted another set of experiments using bacteria and came to the same conclusion as Redi, further supporting the hypothesis that life does not arise spontaneously ([Fig. 1.9](#)).

#### HOW DO WE KNOW?

### FIG. 1.9

## Can microscopic life arise from nonliving matter?

#### BACKGROUND

Educated people in the mid-nineteenth century knew that microbes (microorganisms like bacteria) grow well in nutrient-rich liquids such as broth. It was also known that boiling sterilizes broth, killing the microbes.

#### HYPOTHESIS

Chemist and biologist Louis Pasteur hypothesized that microbes come from microbes and are not spontaneously generated. He argued that if microbes were generated spontaneously from nonliving matter, they would reappear in sterilized broth without the addition of microbes.

#### EXPERIMENT

Pasteur filled two flasks with broth and boiled the broth to sterilize it and kill all the microbes. One flask had a straight neck and one had a swan neck. The straight-neck flask allowed dust particles with microbes to enter. The swan-neck flask did not. As in Redi's experiments ([Fig 1.8](#)), there was only one variable—in this case, the shape of the neck of the flask.

#### RESULTS

Microbes grew in the broth inside the straight-neck flask but not in the swan-neck flask.

## CONCLUSION

The presence of microbes in the straight-neck flask and the absence of microbes in the swan-neck flask supported the hypothesis that microbes come from other microbes and are not spontaneously generated.

## DISCUSSION

Redi's and Pasteur's research illustrate classic attributes of well-designed experiments. Multiple treatments are set up, and nearly all conditions are the same in all of them. These common conditions are constant, so they cannot be the cause of different outcomes of the experiment. One feature—the variable—is changed from one treatment to the next. This is a place to look for explanations of different experimental outcomes.

Redi's and Pasteur's experiments demonstrated that living organisms come from other living organisms. However, this conclusion raises the question of how life arose in the first place. If life comes from life, where did the first living organisms come from? Although today all organisms are produced by parental organisms, early in Earth's history this was not the case. Scientists hypothesize that life initially emerged from chemical compounds and reactions on early Earth about 4 billion years ago. We'll return to the great question of life's origin in [Case 1 Life's Origins](#) and in [Chapters 2](#) through [8](#).

## Self-Assessment Questions

6. What are the first and second laws of thermodynamics, and how do they apply to living organisms?
7. What experimental evidence demonstrates that living organisms come from other living organisms?

## 1.3 THE CELL

The **cell** is the simplest entity that can exist as an independent unit of life. Every known living organism is either a single cell or an ensemble of a few to many cells (**Fig. 1.10**). Most bacteria (like those in Pasteur's experiment), yeasts, and the tiny algae that float in oceans and ponds spend their lives as single cells. In contrast, plants and animals contain billions to trillions of cells that function in a coordinated fashion.

Sources: a. Steve Gschmeissner/Science Source; b. Steve Gschmeissner/Science Source; c. Michael Abbey/Getty Images; d. Sven-Olof Lindblad/Science Source; e. Megapress/Alamy.

FIG. 1.10 Unicellular and multicellular organisms. All living organisms are made up of cells: (a) bacteria; (b) brewer's yeast; (c) algae; (d) cheetahs; (e) humans.

Most cells are tiny, with dimensions that are well below the threshold of detection by the naked eye (**Fig. 1.11**). The cells that make up the layers of your skin (**Fig. 1.11a**) average about 100 micrometers

( $\mu\text{m}$ ), or 0.1 mm, in diameter, which means that nearly 20 would fit in a row across the period at the end of this sentence. Many bacteria are less than a micrometer long. Certain specialized cells, however, can be quite large. Some nerve cells in humans, like the ones pictured in [Fig. 1.11b](#), extend slender projections known as axons for distances as great as a meter, and the cannonball-size egg of an ostrich in [Fig. 1.11c](#) is a single giant cell.

The types of cell just mentioned—bacteria, yeasts, skin cells, nerve cells, and an egg—seem very different, but all are organized along broadly similar lines. In general, all cells contain a stable blueprint of information in molecular form; they have a discrete boundary that separates the interior of the cell from its external environment; and they have the ability to harness materials and energy from the environment.

## Nucleic acids store and transmit information needed for growth, function, and reproduction.

The first essential feature of a cell is its ability to store and transmit information. To accomplish this, cells require a stable archive of information that encodes and helps determine their physical attributes. Just as the construction and maintenance of a house requires a blueprint that defines the walls, plumbing, and electrical wiring, organisms require an accessible and reliable archive of information that helps determine their structure and metabolic activities. Another hallmark of life is the ability to reproduce. To reproduce, cells must be able to copy their archive of information rapidly and accurately. In all organisms, the information archive is a remarkable molecule known as deoxyribonucleic acid, or DNA (Fig. 1.12).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 1.12 A molecule of DNA. DNA is a double helix made up of varying sequences of four different subunits.

DNA is a double-stranded helix, with each strand made up of varying sequences of four different kinds of molecules connected end to end. It is the arrangement of these molecular subunits that makes DNA special; in essence, they provide a four-letter alphabet that encodes cellular information. Notably, the information encoded in DNA directs the formation of **proteins**, the key structural and functional molecules that do the work of the cell. Virtually every aspect of the cell's existence—its internal architecture, its shape, its ability to move, and its various chemical reactions—depends on proteins.

How does the information stored in DNA direct the synthesis of proteins? First, existing proteins create a copy of the DNA's information in the form of a closely related molecule called **ribonucleic acid**, or **RNA**. The synthesis of RNA from a DNA template is called **transcription**, a term that describes the copying of information from one form into another. Specialized molecular structures within the cell then “read” the RNA molecule to determine which building blocks to use to create a protein. This process, called **translation**, converts information stored in the language of nucleic acids to information in the language of proteins.

The pathway from DNA to RNA (specifically to a form of RNA called messenger RNA, or mRNA) to protein is known as the **central dogma** of molecular biology (**Fig. 1.13**). The central dogma describes the basic flow of information in a cell and, while there are exceptions, it constitutes a fundamental principle in biology. As proteins are ultimately encoded by DNA, we can define specific stretches or segments of DNA according to the proteins that they encode. This is the simplest definition of a **gene**: the DNA sequence that corresponds to a specific protein product.

DNA has another remarkable feature. In addition to storing information, it is easily copied, or **replicated**, allowing genetic information to be passed from cell to cell or from an organism to its progeny. Each organism's DNA archive can be stably and reliably passed from generation to generation in large part because of its double-stranded helical structure. During replication, each strand of the double helix serves as a template for a new strand. Replication is necessarily precise and accurate because mistakes introduced into the cell's information archive may be lethal to the cell. That said, errors in DNA can and do occur during the process of replication, and environmental insults can damage DNA as well. Such changes to DNA sequence are known as **mutations**; they can spell death for the cell, or they can lead to the variations that underlie the diversity of life and the process of evolution.

# Membranes define cells and spaces within cells.

The second essential feature of all cells is a [plasma membrane](#) that separates the living material within the cell from the nonliving environment around it ([Fig. 1.14](#)). This boundary between inside and outside does not mean that cells are closed systems independent of the environment. On the contrary, there is an active and dynamic interplay between cells and their surroundings that is mediated by the plasma membrane. All cells require sustained contributions from their surroundings, both simple ions and the building blocks required to manufacture macromolecules. They also release waste products into the environment. As discussed more fully in [Chapter 5](#), the plasma membrane controls the movement of materials into and out of the cell.

In addition to the plasma membrane, many cells have internal membranes that divide the cell into discrete compartments, each specialized for a particular function. A notable example is the [nucleus](#), which houses the cell's DNA. Like the plasma membrane, the nuclear membrane selectively controls movement of molecules into and out of it. As a result, the nucleus occupies a discrete space within the cell, separate from the space outside the nucleus, called the [cytoplasm](#).

Not all cells have a nucleus. In fact, cells can be grouped into two broad classes depending on whether they have a nucleus. Cells without

a nucleus are called [prokaryotes](#), and cells with a nucleus are [eukaryotes](#).

The first cells that emerged about 4 billion years ago were prokaryotic. Their descendants include the familiar bacteria, found today nearly everywhere that life can persist. Some prokaryotes live in peaceful coexistence with humans, inhabiting our gut and aiding digestion ([Case 5 The Human Microbiome](#)). Others cause disease—salmonellosis, tuberculosis, and cholera are familiar examples of such bacterial diseases. The success of prokaryotes depends in part on their small size, their ability to reproduce rapidly, and their ability to obtain energy and nutrients from diverse sources. Most prokaryotes live as single-celled organisms, but some have simple multicellular forms.

Eukaryotes evolved much later, roughly 2 billion years ago, from prokaryotic ancestors. They include familiar groups such as animals, plants, and fungi, along with a wide diversity of single-celled microorganisms called protists. Eukaryotic organisms exist as single cells like yeasts or as multicellular organisms like humans. In multicellular organisms, cells may specialize to perform different functions. For example, in humans, muscle cells contract; red blood cells carry oxygen to tissues; and skin cells provide an external barrier.

The terms “prokaryotes” and “eukaryotes” are useful in drawing attention to a fundamental distinction between these two groups of cells. However, today, biologists recognize three domains of life—[Bacteria](#), [Archaea](#), and [Eukarya](#) ([Chapters 24](#) and [25](#)). Bacteria and Archaea are mostly single-celled microorganisms that lack a

nucleus and are therefore prokaryotes, whereas Eukarya have a nucleus and are eukaryotic. Many Archaea flourish under seemingly hostile conditions, such as those found in the hot springs of Yellowstone National Park.

## Metabolism converts energy from the environment into a form that can be used by cells.

A third key feature of cells is the ability to harness energy from the environment. Let's go back to our introductory example of eating an apple. The apple contains sugars, which store energy in their chemical bonds. By breaking down sugar, our cells harness this energy and convert it into a form that can be used to do the work of the cell. Energy from the food we eat allows us to grow, move, communicate, and do all the other things that we do.

Organisms acquire energy from just two sources—the sun and chemical compounds. The term [metabolism](#) describes chemical reactions by which cells convert energy from one form to another and build and break down molecules. These reactions are required to sustain life. Regardless of their source of energy, all organisms use chemical reactions to break down molecules, in the process releasing energy that is stored in a chemical form called [adenosine triphosphate](#), or [ATP](#). This molecule enables cells to carry out all sorts of work, including growth, division, and moving substances into and out of the cell.

Many metabolic reactions are highly conserved between organisms, meaning the same reactions are found in many different organisms. This observation suggests that the reactions evolved early in the history of life and have been maintained for billions of years because of their fundamental importance to cellular biochemistry.

## A virus is genetic material that requires a cell to carry out its functions.

It's worth taking a moment to consider viruses. A virus is an agent that infects cells. It is usually smaller and simpler than cells. Why, then, aren't viruses the smallest unit of life? We just considered three essential features of cells—the capacity to store and transmit information, a membrane that selectively controls movement in and out, and the ability to harness energy from the environment. Viruses have a stable archive of genetic information, which can be RNA or DNA, surrounded by a protein coat and sometimes a lipid envelope. But viruses cannot harness energy from the environment. Therefore, on their own, viruses cannot read and use the information contained in their genetic material, nor can they regulate the passage of substances across their protein coats or lipid envelopes the way that cells do. To replicate, they require a cell.

A virus infects a cell by binding to the cell's surface, inserting its genetic material into the cell, and, in most cases, using the cellular machinery to produce more viruses. In essence, the virus “hijacks” the cell. Having used the cell's machinery to make more of themselves,

viruses can then lyse, or break, the cell, enabling the new viruses to seek out and infect more cells. In some cases, the genetic material of the virus becomes integrated into the DNA of the host cell.

We discuss viruses many times throughout the book. Each species of Bacteria, Archaea, and Eukarya is susceptible to many types of virus that are specialized to infect its cells. Several hundred types of virus are known to infect humans, and the catalog is still incomplete. Useful tools in biological research, viruses have provided a model system for many problems in biology, including how genes are turned on and off and how cancer develops.

#### Self-Assessment Questions

8. What does it mean to say that a cell is life's functional unit?
9. How does the central dogma help us to understand how mutations in DNA can result in disease?

## 1.4 EVOLUTION

The themes introduced in the last two sections stress life's unity: cells form the basic unit of all life; DNA, RNA, and proteins carry out the molecular functions of all cells; and metabolic reactions build and break down macromolecules. We need only look around us, however, to recognize that for all its unity, life displays a remarkable degree of diversity. We don't really know how many species share our planet, but reasonable estimates run to 10 million or more. Both the unity and the diversity of life are explained by the process of **evolution**, or change over time.

### Variation in populations provides the raw material for evolution.

Described in detail, evolution by **natural selection** calls on complex mathematical formulations, but at heart its main principles are simple, indeed unavoidable. When there is variation within a population of organisms, and when that variation can be inherited (that is, when it can be passed from one generation to the next), the variants best suited for growth and reproduction in a given environment will contribute disproportionately to the next generation. As Darwin recognized, farmers have used this principle for thousands of years to select for crops with high yield or improved resistance to drought and disease. It is how people around the world have developed breeds of dog ranging from terriers to huskies (**Fig. 1.15**). And it is why antibiotic resistance is on the rise in many disease-causing microorganisms. Life has been shaped by evolution since its origin, and the capacity for Darwinian evolution may be life's most fundamental property.

Source: © Rob Brodman 2011.

FIG. 1.15 Artificial selection. Selection over many centuries has resulted in remarkable variations among dogs. Charles Darwin called this “selection under domestication” and noted that it resembles selection that occurs in nature.

The apples in the bin from which you made your choice didn’t all look alike. Had you picked your apple in an orchard, you would have seen that different apples on different trees, or even the same tree, looked different—some smaller, some greener, some misshapen, a few

damaged by worms. Such variation is so commonplace that we scarcely pay attention to it. Variation is observed among individuals in virtually every species of organism. Variation that can be inherited provides the raw material on which evolution acts.

The causes of variation among individuals within a species are usually grouped into two broad categories. Variation among individuals is sometimes due to differences in the environment; this is called **environmental variation**. Among apples on the same tree, some may have good exposure to sunlight; some may be hidden in the shade; some were lucky enough to escape the female codling moth, whose egg develops into a caterpillar that eats its way into the fruit. These are all examples of environmental variation.

The other main cause of variation among individuals is differences in the genetic material that is transmitted from parents to offspring; this is known as **genetic variation**. Differences among individuals' DNA can lead to differences among the individuals' RNA and proteins, which affect the molecular functions of the cell and ultimately can lead to physical differences that we can observe. Genetic differences among apples produce varieties whose mature fruits differ in taste and color, such as the green Granny Smith, the yellow Golden Delicious, and the scarlet Red Delicious.

But even on a single tree, each apple contains seeds that are genetically distinct because the apple tree is a sexual organism. Bees carry pollen from the flowers of one tree and deposit it in some of the flowers of another, enabling the sperm inside pollen grains to fertilize

egg cells within that single flower. All the seeds on an apple tree contain shared genes from one parent, the tree on which they developed. But they contain distinct sets of genes contributed by sperm transported in pollen from other trees. In all sexual organisms, fertilization produces unique combinations of genes, which explains in part why sisters and brothers with the same parents can be so different from one another.

Genetic variation ultimately stems from mutations. Mutations arise either from random errors during DNA replication or from environmental factors such as ultraviolet (UV) radiation, which can damage DNA. If these mutations are not corrected, they are passed on to the next generation. To put a human face on this, consider that lung cancer can result from an environmental insult, such as cigarette smoking, or from a genetic susceptibility inherited from the parents.

In nature, most mutations that harm growth and reproduction die out after a handful of generations. Those that are neither harmful nor beneficial can persist for hundreds or thousands of generations. And those that are beneficial to growth and reproduction can gradually become incorporated into the genetic makeup of every individual in the species. That is how evolution works: the genetic makeup of a population changes over time.

**Evolution predicts a nested pattern of relatedness among species, depicted as a tree.**

Evolutionary theory predicts that new species arise by the divergence of populations through time from a common ancestor. As a result, closely related species are likely to resemble each other more closely than they do more distantly related species. You know this to be true from common experience. All of us recognize the similarity between a chimpanzee's face and body and our own ([Fig. 1.16a](#)), and biologists have long known that we humans share more features with chimpanzees than we do with any other species.

Humans and chimpanzees, in turn, share more features with gorillas than they do with any other species. And humans, chimpanzees, and gorillas share more features with orangutans than they do with any other species. And so on. We can continue to include a widening diversity of species, successively adding monkeys, lemurs, and other

primates, to construct a set of evolutionary relationships that can be depicted as a tree ([Fig. 1.16b](#)). In this tree, the tips or branches on the right represent different groups of organisms, nodes (where lines split) represent the most recent common ancestor, and time runs from left to right.

Evolutionary theory predicts that primates should show a nested pattern of similarity, and this is indeed what morphological and molecular observations reveal. We can continue to add other mammals and then other vertebrate animals to our comparison, in the process generating a pattern of evolutionary relationships that forms a larger tree, with the primates confined to one limb. Using comparisons of DNA among species, we can then generate still larger trees, ones that include plants as well as animals and the full diversity of microscopic organisms. Biologists call the full set of evolutionary relationships among all organisms the tree of life.

This tree, illustrated in [Fig. 1.17](#), has two major branches, one made up of Bacteria and the other consisting of Archaea and Eukarya. Although eukaryotes include large multicellular organisms such as humans, most branches on the tree of life consist of microorganisms. The last common ancestor of all living organisms, which forms a root to the tree, is thought to lie between the branch leading to Bacteria and the branch leading to Archaea and Eukarya. The tree shows that eukaryotes arose from within the Archaea, but the origin of eukaryotic cells may be more complicated than that. The Eukarya is now thought by many biologists to have originated from a partnership, or symbiosis, between an archaeon and a bacterium. (We'll explore this hypothesis

more fully in [Chapter 25](#).) One feature of the tree of life that everyone accepts is that the plants and animals so conspicuous in our daily existence make up only two branches on the eukaryotic limb of the tree.

The tree of life makes predictions for the order of appearance of different life-forms in the history of life, documented in rock in the fossil record. For example, [Fig. 1.16](#)—one small branch on the greater tree—predicts that humans should appear later in the fossil record than monkeys, and that primates more akin to lemurs and tarsiers should appear even earlier. The greater tree also predicts that all records of animal life should be preceded by a long interval of microbial evolution. As we will see in subsequent chapters, these predictions are confirmed by the geologic record.

Shared features, then, sometimes imply inheritance from a common ancestor. In combination, fossils and molecular studies such as comparisons of DNA sequences show that the close similarity between humans and chimpanzees reflects descent from a common ancestor that lived about 6 million years ago. Their differences reflect what Darwin called “descent with modification”—evolutionary changes that have accumulated over time since the two lineages split. For example, as discussed in [Chapter 23](#), the flat face of humans, our small teeth, and our upright posture all evolved within our ancestors after they diverged from the ancestors of chimpanzees. At a broader scale, the fundamental features shared by all organisms reflect inheritance from a common ancestor that lived billions of years ago. Moreover, the differences that characterize the many branches on the tree of life have formed through the continuing action of evolution *since* the time of our earliest ancestors.

Four decades ago, the geneticist Theodosius Dobzhansky wrote, “Nothing in biology makes sense except in the light of evolution.” For this reason, evolution permeates discussions throughout this book, whether we are explaining the molecular biology of cells, how organisms function and reproduce, how species interact in nature, or the remarkable biological diversity of our planet.

## Evolution can be studied by means of experiments.

Both the nested patterns of similarity among living organisms and the succession of fossils in the geologic record fit the predictions of evolutionary theory. But can we capture evolutionary processes in

action? One way to accomplish this goal is in the laboratory. Bacteria are ideal for these experiments because they reproduce rapidly and can form populations with millions of individuals. Large population size means that mutations are likely to form in nearly every generation, even though the probability that any individual cell will acquire a mutation is small. (In contrast to bacteria, think about trying evolutionary experiments on elephants!)

One such experiment is illustrated in [Fig. 1.18](#). Beginning in 1988, microbiologist Richard Lenski grew populations of the common intestinal bacterium *Escherichia coli* in liquid medium containing small amounts of the sugar glucose as the only source of food. Lenski and his colleagues hypothesized that any bacterium with a mutation that increased its ability to use glucose would grow and reproduce at a faster rate than other bacteria in the population. In this experiment, then, they asked: did bacteria from later generations grow and reproduce more rapidly than those of earlier generations—that is, did evolution occur?

#### HOW DO WE KNOW?

### FIG. 1.18

## Can evolution be demonstrated in the laboratory?

#### BACKGROUND

*Escherichia coli* is an intestinal bacterium commonly used in the laboratory. In 1988, the biologist Richard Lenski asked whether *E. coli* grown generation after generation on a medium containing limiting amounts of glucose as food would evolve in ways that improved their

ability to metabolize this compound.

#### HYPOTHESIS

Any bacterium with a random mutation that increases its ability to take up and utilize glucose will reproduce at a faster rate than other bacteria in the population. Over time, such a mutant will increase in frequency relative to other types of bacteria, thereby demonstrating evolution in a bacterial population.

#### EXPERIMENT

Cells of *E. coli* can be frozen at  $-80$  degrees Celsius, which keeps them in a sort of suspended animation in which no biological processes take place, but the cells survive. At the beginning of the experiment, Lenski and his students froze samples of the starting bacteria (“Ancestral”). As the experiment progressed, they took samples of the bacterial populations every 500 generations (“Later”) and grew them together with a thawed sample of the starting bacteria on glucose-containing medium. They then compared the rate of growth of the ancestral bacteria with that of the bacteria samples taken at later time points.

#### RESULTS

Through time, the cells from later time points grew increasingly more rapidly than the ancestral cells when the two populations were grown together on the glucose medium.

## CONCLUSION

Evolution occurred in the population: the *E. coli* bacteria evolved an improved ability to metabolize glucose.

## FOLLOW-UP WORK

As of 2017, the experiment has continued for more than 60,000 generations. Taking advantage of new genomic tools, Lenski and colleagues have been able to characterize increases in fitness in terms of specific mutations and follow the fate of individual genes through time.

SOURCES (experiment diagram) Elena, S. F., and R. E. Lenski. 2003. "Evolution Experiments with Microorganisms." *Nature Review Genetics* 4:457–469; (graph) Lenski, R. E. 2017. "Experimental Evolution and the Dynamics of Adaptation and Genome Evolution in Microbial Populations." *The ISME Journal* 11:2181–2194.

In fact, the bacteria did evolve an improved ability to use glucose, as demonstrated by the results shown in [Fig. 1.18](#). This experiment both illustrates how experiments can be used to test hypotheses and shows evolution in action. Furthermore, follow-up studies of the bacterial DNA identified differences in genetic makeup that resulted in the improved ability of *E. coli* to use glucose. Many experiments of this general type have been carried out, applying scientific inquiry to demonstrate how bacteria adapt through mutation and natural selection to any number of environments.

Experiments in laboratory evolution help us understand how life works, and they have an immensely important practical side. They allow biologists to develop new and beneficial strains of microorganisms that, for example, remove toxins from lakes and rivers. In addition, they show how some of our worst pathogens develop resistance to drugs designed to eliminate them.

#### Self-Assessment Questions

10. How does evolution account for both the unity and the diversity of life?
11. How might the heavy-handed use of antibiotics result in the increase of antibiotic-resistant cells in bacterial populations?

## 1.5 ECOLOGICAL SYSTEMS

When watching a movie, we don't need a narrator to tell us whether the action is set in a tropical rain forest, the African savanna, or the Arctic tundra. The plants in the scene make it obvious. Plants can be linked closely with environment—palm trees with the tropics, for example, or cacti with the desert—because the environmental distributions of different species reflect the sum of their biological features. Palms cannot tolerate freezing and so are confined to warmer environments; the cactus can store water in its tissues, enabling it to withstand prolonged drought. But the geographic ranges of palms and cacti reflect more than just their physical tolerances. They are also strongly influenced by interactions with other species, including other plants that compete for the limited resources available for growth, animals that feed on them or spread their pollen, and microorganisms that infest their tissues. **Ecology** is the study of how organisms interact with one another and with their physical environment in nature.

### Basic features of anatomy, physiology, and behavior shape ecological systems.

Apple trees, we noted, reproduce sexually. How is this accomplished, given that the trees have no moving parts? The answer is that bees carry pollen from one flower to the next, enabling sperm carried within the pollen grain to fuse with an egg cell protected within the flower (**Fig. 1.19**). The process is much like the one discussed at the beginning of the chapter in which hummingbirds carry pollen from

flower to flower. In both examples, the plants complete their life cycles by exploiting close interactions with animal species. Birds and bees visit flowers, attracted, as we are, by their color and odor. Neither visits flowers with the intent to pollinate; they come in expectation of a meal. As the birds and bees nestle into flowers to collect nutritious nectar, pollen rubs off on their bodies.

*Source: Donald Specker/Animals Animals – Earth Scenes.*

FIG. 1.19 Bee pollination. Many plants reproduce sexually by exploiting the behavior of animals. Here a honeybee pollinates an apple flower.

But if animals help apples to fertilize their eggs, how do apple trees disperse from one site to another? Again, the plants rely on animals—the apple's flesh attracts mammals that eat the fruit, seeds and all, and spread the seeds through defecation. Humans tend to be finicky—we carefully eat only the sweet outer flesh, discarding the seedy core.

Nonetheless, even as humans have selected apples for their quality of fruit, we have dispersed apple trees far beyond their natural range.

The many ways that organisms interact in nature reflect their basic functional requirements. If a plant is to grow and reproduce, for example, it must have access to light, carbon dioxide, water, and basic nutrients. All plants have these requirements, so one plant's success in gathering nutrients may mean that fewer nutrients are available for its neighbor—the plants may compete for limited resources needed for growth ([Fig. 1.20a](#)). Animals in the same area require organic molecules for nutrition, and some of them may eat the plant's leaves or bark ([Fig. 1.20b](#)). Predation also benefits some organisms at the expense of others. In combination, the physical tolerances of organisms and the ways that organisms interact with one another determine the structure and diversity of communities.

Sources: a. Louise Murray/Getty Images; b. Gail Shumway/Getty Images.

FIG. 1.20 Ecological relationships. (a) The trees in a rain forest all require water and nutrients. Neighboring plants compete for the limited supplies of these

materials. (b) Plants provide food for many animals. Leaf-cutter ants cut slices of leaves from tropical plants and transport them to their nests, where the leaves grow fungi that the ants eat.

In short, ecological relationships reflect the biomechanical, physiological, and behavioral traits of organisms in nature. Form and function, in turn, arise from molecular processes within cells, governed by the expression of genes.

## Ecological interactions play an important role in evolution.

G. Evelyn Hutchinson, one of the founders of modern ecology, wrote a book called *The Ecological Theater and the Evolutionary Play* (1965). This wonderful title succinctly captures a key feature of biological relationships: it suggests that ecological communities provide the stage on which the play of evolution takes place.

As an example, let's look again at plants competing for resources. As a result of this competition, natural selection may favor plants that have more efficient uptake of nutrients or water. In the example of animals eating plants, natural selection may favor animals with greater jaw strength or more efficient extraction of nutrients in the digestive system. In turn, plants that avoid predation by synthesizing toxic compounds in their leaves may gain the upper hand. In each case, interactions between organisms lead to the evolution of particular traits.

Consider another example from mammal–plant interactions:

selection for fleshy fruits improved the dispersal of apples because it increased the attractiveness of these seed-bearing structures to hungry mammals. Tiny yeasts make a meal on sugary fruits as well, in the process producing alcohol that deters potential competitors for the food. Humans learned to harness this physiological capability of yeasts in prehistoric times, and for this reason the total abundance and distribution of *Vitis vinifera*, the wine grape, has increased dramatically through time.

Self-Assessment Question

12. What are the features that determine the shape of ecological systems?

## 1.6 THE HUMAN FOOTPRINT

The story of life has a cast of millions, with humans playing only one of the many roles in an epic 4 billion years in the making. *Homo sapiens* has existed for only the most recent 1/200 of 1% of life's history, yet there are compelling reasons to pay special attention to our own species. We want to understand how our own bodies work and how humans came to be: curiosity about ourselves is, after all, a deeply human trait.

We also want to understand how biology can help us conquer disease and improve human welfare. Epidemics have decimated human populations throughout history. The Black Death—bubonic plague caused by the bacterium *Yersinia pestis*—is estimated to have killed half the population of Europe in the fourteenth century. Casualties from the flu pandemic of 1918 exceeded those of World War I. Even King Tut, we now know, suffered from malaria in his Egyptian palace approximately 3300 years ago. Throughout this book, we discuss how basic biological principles are helping scientists to prevent and cure the great diseases that have persisted since antiquity, as well as modern ones such as AIDS and Ebola.

Furthermore, we need to understand the evolutionary and ecological consequences of a human population that now exceeds 7 billion. All species affect the world around them. However, in the twenty-first century human activities have taken on special importance because our numbers and technological abilities make our footprint on Earth's ecology so large. Human activities now emit more carbon dioxide than do volcanoes, through industrial processes we convert more

atmospheric nitrogen to ammonia than nature does, and we commandeer, either directly or indirectly, as much as 25% of all photosynthetic production on land. To chart our environmental future, we need to understand our role in the Earth system as a whole.

And, as we have become major players in ecology, humans have become important agents of evolution. As our population has expanded, some species have expanded along with us ([Fig. 1.21](#)). We've seen how humans' pursuit of agriculture sharply increased the abundance and distribution of grapes, and the same is true for corn, cows, and apple trees. At the same time, we have inadvertently helped other species to expand—the crowded and not always clean environments of cities provide excellent habitats for cockroaches and rats.

FIG. 1.21 Humans as agents of evolution. Species that have benefited from human activity include (a) corn, (b) rats, and (c) cockroaches.

Other species are in decline, their populations reduced by hunting and fishing, changes in land use, and other human activities ([Fig. 1.22](#)). When Europeans first arrived on the Indian Ocean island of Mauritius, large flightless birds called dodos were plentiful. Within a century, the dodo was extinct. Early Europeans in North America were greeted by vast populations of passenger pigeons, more than a million in a single flock. By the early twentieth century, the species had disappeared, a victim of hunting and habitat change through expanding agriculture. Other organisms both great (the Bali tiger) and small (the dusky seaside sparrow) have become extinct in recent decades. Still others are imperiled by human activities: victimized by habitat destruction and poaching, the last surviving male of the Northern White Rhinoceros died in 2018. Whether any rhinos will exist at the end of this century will depend almost entirely on decisions we make today.

FIG. 1.22 Extinct and endangered species. Humans have caused many organisms to become extinct, such as (a) the dodo, (b) passenger pigeon, (c) Bali tiger, and (d) dusky seaside sparrow. Burgeoning human populations have diminished the ranges of many others, including (e) the white rhinoceros.

Throughout this book, we return to the practical issues of life science. How can we use the principles of biology to improve human welfare, and how can we live our lives in ways that control our impact on the world around us? The answers to the questions critically depend on understanding biology in an *integrated* fashion. While it is tempting to consider molecules, cells, organisms, and ecosystems as separate entities, they are inseparable in nature. To tackle biological problems—

whether building an artificial cell, stopping the spread of infectious diseases such as HIV or malaria, feeding a growing population, or preserving endangered habitats and species—we need an integrated perspective. In decisively important ways, our future welfare depends on improving our knowledge of how life works.

### Self-Assessment Questions

13. What are three ways that humans have affected life on Earth?
14. What are the six themes that are discussed in this chapter?  
Summarize each one.

## CORE CONCEPTS SUMMARY

**1.1 SCIENTIFIC INQUIRY:** Scientific inquiry is a deliberate way of asking and answering questions about the natural world.

Observations are used to generate a hypothesis, a tentative explanation that makes predictions that can be tested. [page 4](#)

On the basis of a hypothesis, scientists design experiments and make additional observations that test the hypothesis. [page 4](#)

A controlled experiment typically involves several groups in which all the conditions are the same and one group where a variable is deliberately introduced to determine whether that variable has an effect. [page 5](#)

Scientific inquiry involves making observations, asking questions, doing experiments or making further observations, and drawing and sharing conclusions. [page 6](#)

If a hypothesis is supported through continued observation and experiments over long periods of time, it is elevated to a theory, a sound and broad explanation of some aspect of the world. [page 7](#)

**1.2 CHEMICAL AND PHYSICAL PROPERTIES:** Life works according to fundamental principles of chemistry and physics.

The living and nonliving worlds follow the same chemical rules and obey the same physical laws. [page 8](#)

Experiments by Redi in the 1600s and Pasteur in the 1800s demonstrated that organisms come from other organisms and are

not spontaneously generated. [page 10](#)

Life originated on Earth about 4 billion years ago, arising from nonliving matter. [page 11](#)

### **1.3 THE CELL:** The fundamental unit of life is the cell.

The cell is the simplest biological entity that can exist independently. [page 11](#)

Information in a cell is stored in the form of the nucleic acid DNA. [page 13](#)

The central dogma describes the usual flow of information in a cell, from DNA to RNA to protein. [page 13](#)

The plasma membrane is the boundary that separates the cell from its environment. [page 13](#)

Cells with a nucleus are eukaryotes; cells without a nucleus are prokaryotes. [page 14](#)

Metabolism is the set of chemical reactions in cells that build and break down macromolecules and harness energy. [page 14](#)

A virus is an infectious agent composed of a genome and protein coat that uses a host cell to replicate. [page 15](#)

### **1.4 EVOLUTION:** Evolution explains the features that organisms share and those that set them apart.

When variation is present within a population of organisms, and when that variation can be inherited, the variants best able to grow

and reproduce in a particular environment will contribute disproportionately to the next generation, leading to a change in the population over time, or evolution. [page 15](#)

Variation can be genetic or environmental. The ultimate source of genetic variation is mutation. [page 16](#)

Organisms show a nested pattern of similarity, with humans being more similar to primates than other organisms, primates being more similar to mammals, mammals being more similar to vertebrates, and so on. [page 16](#)

Evolution can be demonstrated by laboratory experiments. [page 17](#)

**1.5 ECOLOGICAL SYSTEMS:** Organisms interact with one another and with their physical environment, shaping ecological systems that sustain life.

Ecology is the study of how organisms interact with one another and with their physical environment in nature. [page 19](#)

These interactions are driven in part by the anatomy, physiology, and behavior of organisms—that is, the basic features of organisms shaped by evolution. [page 19](#)

**1.6 THE HUMAN FOOTPRINT:** In the twenty-first century, humans have become major agents in ecology and evolution.

Humans have existed for only the most recent 1/200 of 1% of life's 4-billion-year history. [page 21](#)

In spite of humans' recent arrival on the planetary scene, our

growing numbers are leaving a large ecological and evolutionary footprint. [page 21](#)

Solving biological problems requires an integrated understanding of life, with contributions from all the fields of biology, including molecular biology, cell biology, genetics, organismal biology, and ecology, as well as from chemistry, physics, and engineering. [page 23](#)

## CASE 1

### Life's Origins

*Information, Homeostasis, and Energy*

The walls of Endurance crater expose sandstones deposited on the surface of Mars more than 3 billion years ago. These sandstones provide information about Mars' surface environment around the same time that life was gaining a foothold on Earth. Most of the sands were deposited by wind, but thin rippled beds near the top of the crater indicate that some of the sands were transported by water. Further evidence for water on Mars comes from the chemistry of the beds. Most grains are made of salts, indicating that volcanic rocks interacted with water for many years, dissolving some minerals and precipitating others. Among the salts is a mineral called jarosite, known on Earth from acid mine waste and other environments where the pH is low. Iron oxides also tell us that a small amount of oxygen gas existed in the ancient atmosphere of Mars.

Photo Source: NASA/JPL/Cornell

**Endurance crater.** Analysis of ancient sedimentary rocks exposed in the walls of this crater and others on Mars provides clues to what the environment was like on early Mars. Could life thrive under such conditions? Could it originate under such conditions?

Could life have existed on the young Mars? On Earth, some microorganisms thrive in environments that are similar to the environment recorded by rocks at Endurance crater. As yet we have no evidence of ancient organisms on Mars, but maybe—just maybe—life could have subsisted in the arid, acidic, and oxidizing setting recorded by Endurance rocks. At the time the Endurance rocks formed, Mars was growing drier and colder, but older sedimentary rocks found elsewhere on the planet indicate that there were once lakes and streams that persisted for many thousands of years. Whether organisms could *thrive* in the environments that existed on early Mars is one question; whether life could *originate* under these conditions is another.

When and how life originated are some of the biggest questions in biology. They are as central to understanding our own planet as they are for Mars. Earth is nearly 4.6 billion years old. Chemical evidence

from 3.5-billion-year-old rocks in Australia indicates that biologically based carbon and sulfur cycles existed at the time those rocks formed. Because living organisms drive these cycles, life must have originated earlier. Evidence from other continents appears to push the origin of life back to 3.8 billion years or even earlier. In the eons since then, the first primitive life-forms have evolved into the millions of different species that populate Earth today.

*All cells require an archive of information, a membrane to separate the inside of the cell from its surroundings, and the ability to gather materials and harness energy from the environment.*

How did the first living cell arise?  
Scientists generally accept that life arose from nonliving materials—a process called abiogenesis—and thousands of laboratory experiments performed over the

last sixty years provide glimpses of how this might have occurred. In our modern world, the features that separate life from nonlife are relatively easy to discern. However, Earth's first organisms were almost certainly much less complex than even the simplest bacteria alive today. And before those first living organisms appeared, molecular systems presumably existed that hovered somewhere between the living and the nonliving.

All cells require an archive of information, a membrane to separate

the inside of the cell from its surroundings, and the ability to gather materials and harness energy from the environment. In modern organisms, the cell's information archive is deoxyribonucleic acid (DNA), the double-stranded molecule that contains the instructions needed for cells to grow, differentiate, and reproduce. Without nucleic acids like DNA, life as we know it would not exist.

DNA is critical to life as we know it, and it is complex. Among the organisms alive today, the smallest known genome belongs to the bacterium *Carsonella rudii*. Even that genome contains nearly 160,000 DNA base pairs. How could such sophisticated molecular systems have arisen?

The likely answer to that question is “step by step.” Laboratory experiments have shown how precursors to nucleic acids might have formed and interacted under the chemical conditions present on the young Earth. It's exceedingly unlikely that a molecule as complex as DNA was used by the very first living cells. As you'll see in the chapters that follow, scientists have gathered evidence suggesting that RNA, rather than DNA, stored information in early cells. Very likely, RNA performed other functions in early cells as well, catalyzing chemical reactions much as proteins do today.

While some kind of information archive was necessary for life to unfold, there is more to the story. Living things must have a barrier that separates them from their environment. All cells, whether found as single-celled bacteria or by the trillions in trees or humans, are individually encased in a cell membrane.

Once again, scientists can only guess at how the first cell membranes came about, but research shows that the molecules that make up modern membranes possess properties that may have led them to form spontaneously on the early Earth. At first, the membranes were probably quite simple—straightforward (but leaky) barriers that kept the contents of early cells separated from the world at large. Over time, as chance variations arose, those membranes that provided a better barrier were favored by natural selection. Moreover, proteins became embedded in membranes, providing gates or channels that regulated the transport of ions and small molecules into and out of the cell. In this way, early organisms gained the capacity to regulate cell interiors—what biologists call homeostasis.

A third essential characteristic of living things is the ability to harness energy from the environment. Here, too, a series of natural chemical processes might have led to cells that could achieve this feat. Simple reactions that produced carbon-bearing molecular by-products would have enabled more complex reactions down the road. Ultimately, that collection of reactions—combined with an archive of information and enclosed in some kind of primitive membrane—evolved into individual units that could grow, reproduce, and evolve.

Such a series of events may sound unlikely. However, some scientists argue that given the chemicals present on the early Earth, it was likely—perhaps even inevitable—that they would come together in such a way that life would emerge. Indeed, relatively simple, naturally occurring materials such as metal ions have been shown to play a role in key cellular reactions. Billions of years after the first cells

arose, some of those metal ions—such as complexes of iron and sulfur—still play a critical role in cells.

One way to investigate how life originated is to mimic in the laboratory environmental conditions of the early Earth and analyze what compounds are produced. A different approach involves the study of extremophiles—organisms that live and even thrive in extreme environments, such as deep-sea hydrothermal vents. These studies can help us understand how life might have originated and evolved in early environments quite different from those we typically experience today.

*Source: Image courtesy of New Zealand American Submarine Ring of Fire 2007 Exploration, NOAA Vents Program, the Institute of Geological & Nuclear Sciences and NOAA-OE.*

A hydrothermal vent. Some scientists think that this type of vent provided a favorable environment for chemical reactions that led to the origin of life on Earth.

Did life arise just once? Or could it have started up and died out several times before it finally got a firm foothold? If, given Earth's early chemistry, life on our planet was inevitable, or at least probable, could it have arisen elsewhere in the universe? Indeed, might life have originated on our neighbor Mars? The study of life's origins produces many more questions than answers—and not just for biologists. The mystery of life spans the fields of biology, chemistry, physics, and planetary science. Though the questions are vast, our understanding of life's origins is likely to come about the same way life itself arose: step by step.

## DELVING DEEPER INTO CASE 1

**For each of the Cases, we provide a set of questions to pique your curiosity. These questions cannot be answered directly from the Case itself, but instead introduce issues that will be addressed in chapters to come. We revisit this case in [Chapters 2–8](#) on the pages indicated below.**

1. How did the molecules of life form? See [page 45](#).
2. What kinds of nucleic acids were present in the earliest cells? See [page 60](#).
3. How did the genetic code originate? See [page 85](#).

4. How did the first cell membranes form? See [page 95](#).
  5. Which naturally occurring elements might have spurred the reactions that led to the emergence of life? See [page 131](#).
  6. What were the earliest energy-harnessing reactions? See [page 143](#).
  7. How did early cells meet their energy requirements? See [page 149](#).
  8. How did early cells use sunlight to meet their energy requirements? See [page 173](#).

## CHAPTER 2 The Molecules of Life

LOOK Die Bildagentur der Fotografen GmbH/Alamy

---

### CORE CONCEPTS

**2.1 PROPERTIES OF ATOMS:** The atom is the fundamental unit of matter.

**2.2 MOLECULES AND CHEMICAL BONDS:** Atoms can combine to

form molecules linked by chemical bonds.

**2.3 WATER:** Water is essential for life.

**2.4 CARBON:** Carbon is the backbone of organic molecules.

**2.5 ORGANIC MOLECULES:** Organic molecules include proteins, nucleic acids, carbohydrates, and lipids, each of which is built from simpler units.

**2.6 LIFE'S ORIGINS:** Life likely originated on Earth by a set of chemical reactions that gave rise to the molecules of life.

---

When biologists speak of diversity, they commonly point to the 2 million or so species named and described to date, or to the 10–100 million living species thought to exist in total. Life's diversity can also be found at a very different level of observation: in the molecules within cells. Life depends critically on many essential functions, including storing and transmitting genetic information, establishing a boundary to separate cells from their surroundings, and harnessing energy from the environment. These functions ultimately depend on the chemical characteristics of the molecules that make up cells and organisms.

In spite of the diversity of molecules and functions, the chemistry of life is based on just a few types of molecule, which in turn are made up of just a few elements. Of the 100 or so chemical elements, only about a dozen are found in more than trace amounts in living organisms. These elements interact with one another in only a limited number of ways. So, the question arises: how is diversity generated from a limited

suite of chemicals and interactions? The answer lies in some basic features of chemistry.

## 2.1 PROPERTIES OF ATOMS

Since antiquity, it has been accepted that the materials of nature are made up of a small number of fundamental substances combined in various ways. Today, we call these substances **elements**. From the seventeenth century through the end of the nineteenth century, elements were defined as pure substances that could not be broken down further by the methods of chemistry. In time, it was recognized that each element contains only one type of **atom**, the basic unit of matter. By 1850, about 60 elements were known, including such common ones as oxygen, copper, gold, and sodium. Today, 118 elements are known. Of these, 94 occur naturally and 24 have been created artificially in the laboratory. Elements are often indicated by a chemical symbol that consists of a one- or two-letter abbreviation of the name of the element. For example, carbon is represented by C, hydrogen by H, and helium by He.

### Atoms consist of protons, neutrons, and electrons.

Elements are composed of atoms. The atom contains a dense central **nucleus** made up of positively charged particles called **protons** and electrically neutral particles called **neutrons**. A third type of particle, the negatively charged **electron**, moves around the nucleus at some distance from it. Carbon, for example, typically has six protons, six neutrons, and six electrons (**Fig. 2.1**). The number of protons, or the atomic number, specifies an atom as a particular element. An atom with one proton is hydrogen, for example, and an atom with six protons is carbon.

Together, the protons and neutrons determine the [atomic mass](#), the mass of the atom. Each proton and neutron, by definition, has a mass of 1, whereas an electron has negligible mass. The number of neutrons in atoms of a particular element can differ, changing its mass. [Isotopes](#) are atoms of the same element that have different numbers of neutrons. For example, carbon has three isotopes: approximately 99% of carbon atoms have six neutrons and six protons, for an atomic mass of 12; approximately 1% have seven neutrons and six protons, for an atomic mass of 13; and only a very small fraction have eight neutrons and six protons, for an atomic mass of 14. The atomic mass is sometimes

indicated as a superscript to the left of the chemical symbol. For instance,  $^{12}\text{C}$  is the isotope of carbon with six neutrons and six protons.

Typically, an atom has the same number of protons and electrons. Because a carbon atom has six protons and six electrons, the positive and negative charges cancel each other out and the carbon atom is electrically neutral. Some chemical processes cause an atom to either gain or lose electrons. An atom that has lost an electron is positively charged, and one that has gained an electron is negatively charged. Electrically charged atoms are called **ions**. The charge of an ion is specified as a superscript to the right of the chemical symbol. Thus,  $\text{H}^+$  indicates a hydrogen ion that has lost an electron and is positively charged.

## Electrons occupy regions of space called orbitals.

Electrons move around the nucleus, but not in the simplified way shown in [Fig. 2.1](#). The exact path that an electron takes cannot be known, but it is possible to identify a region in space, called an **orbital**, where an electron is present most of the time. For example, [Fig. 2.2a](#) shows the orbital for hydrogen, which is simply a sphere occupied by a single electron. Most of the time, the electron is found within the space defined by the sphere, although its exact location at any instant is unpredictable.

FIG. 2.2 Electron orbitals and energy levels (shells) for hydrogen and carbon.

The orbital of an electron can be visualized as a cloud of points that is denser where the electron is more likely to be. The hydrogen atom contains a single orbital, in a single energy level (a and c). The carbon atom has five orbitals, one in the first energy level and four in the second energy level (b and c). In the second energy level, electrons in the spherical orbital have slightly less energy than those in the dumbbell-shaped orbitals.

The maximum number of electrons in any orbital is two. Most atoms have more than two electrons, so they have several orbitals occupied by electrons that are positioned at different distances from the nucleus. These orbitals differ in size and shape. Electrons in orbitals close to the nucleus have less energy than do electrons in orbitals farther away. An analogy can help to explain this concept. When you bike up a hill, part of the energy you expend is stored in the increased elevation of you and the bike, and you get some of that stored energy back again when you coast down the hill. The elevation of the bike is analogous to the distance of an electron from the nucleus. An electron gives up energy when it moves to a closer orbital, which is why

electrons fill up orbitals close to the nucleus before occupying those farther away. Several orbitals can exist at a given energy level, or **shell**. The first shell consists of the spherical orbital shown in [Fig. 2.2a](#).

[Fig. 2.2b](#) shows the electron orbitals for carbon. Of carbon's six electrons, two occupy the small spherical orbital representing the lowest energy level. The remaining four are distributed among four possible orbitals at the next highest energy level: one of these four orbitals is a sphere (larger in diameter than the orbital at the lowest energy level) and three are dumbbell-shaped. In carbon, the outermost spherical orbital has two electrons, two of the dumbbell-shaped orbitals have one electron each, and one of the dumbbell-shaped orbitals is empty. Because a full orbital contains two electrons, it would take a total of four additional electrons to completely fill all of the orbitals at this energy level. Therefore, after the first shell, the maximum number of electrons per energy level is eight. [Fig. 2.2c](#) shows simplified diagrams of atoms in which the highest energy level, or shell, of hydrogen, represented by the outermost circle, contains one electron, and that of carbon contains four electrons.

## Elements have recurring, or periodic, chemical properties.

The chemical elements are often arranged in a tabular form known as the **periodic table of the elements**, shown in [Fig. 2.3](#). The development of the periodic table is generally credited to the nineteenth-century Russian chemist Dmitri Mendeleev. The table provides a way to organize all the chemical elements in terms of their chemical properties.

Morris, *Biology: How Life Works*, 3e. © 2019 W. H. Freeman and Company

In the periodic table, the elements are indicated by their chemical symbols and arranged in order of increasing atomic number. For example, the second row of the periodic table begins with lithium (Li) with 3 protons and ends with neon (Ne) with 10 protons.

274

FIG. 2.4 Energy levels (shells) of row 2 of the periodic table. The complete complement of electrons in the outer shell of this row of elements is eight.

The elements in a vertical column are called a group or family. Members of a group all have the same number of electrons in their outermost shell. For example, carbon (C) and lead (Pb) both have four electrons in their outermost shell. The number of electrons in the outermost shell determines in large part how elements interact with other elements to form a diversity of molecules, as we will see in the next section.

#### Self-Assessment Questions

1. In the early 1900s, Ernest Rutherford produced a beam of very small positive particles and directed it at a thin piece of gold foil just a few atoms thick. Most of the particles passed through the foil without changing their path; very rarely, a particle was deflected. What conclusions can you draw from this experiment about the structure of an atom?
2. What are atoms made up of? Describe each component.
3. What is the logic behind how the periodic table of the elements is organized?

## 2.2 MOLECULES AND CHEMICAL BONDS

Atoms can combine with other atoms to form **molecules**, which are groups of two or more atoms attached together that act as a single unit. When two atoms form a molecule, the individual atoms interact through what is called a **chemical bond**, a form of attraction between atoms that holds them together. The ability of atoms to form bonds with other atoms explains in part why just a few types of element can come together in many different ways to make a variety of molecules that can carry out diverse functions in a cell. There are several ways in which atoms can interact with one another, and therefore many different types of chemical bond.

### A covalent bond results when two atoms share electrons.

The ability of atoms to combine with other atoms is determined in large part by the electrons farthest from the nucleus—those in the outermost orbitals of an atom. These electrons are called **valence electrons**, and they are at the highest energy level of the atom. When atoms combine with other atoms to form a molecule, the atoms share valence electrons with each other. Specifically, when the outermost orbitals of two atoms come into proximity to each other, two atomic orbitals each containing one electron merge into a single orbital containing a full complement of two electrons. The merged orbital is called a **molecular orbital**, and each shared pair of electrons constitutes a **covalent bond** that holds the atoms together.

We can represent a specific molecule by its chemical formula, which is written as the letter abbreviation for each element followed by a subscript giving the number of that type of atom in the molecule. Among the simplest molecules is hydrogen gas, illustrated in [Fig. 2.5](#), which consists of two covalently bound hydrogen atoms as indicated by the chemical formula  $\text{H}_2$ . Each hydrogen atom has a single electron in a spherical orbital. When the atoms join into a molecule, the two orbitals merge into a single molecular orbital containing two electrons that are shared by the hydrogen atoms. A covalent bond between atoms is denoted by a single line connecting the two chemical symbols for the atoms, as shown in the structural formula in [Fig. 2.5](#).

Two adjacent atoms can sometimes share two pairs of electrons, forming a [double bond](#) denoted by a double line connecting the two chemical symbols for the atoms. In this case, four orbitals, each

occupied by a single electron, merge to form two molecular orbitals.

Molecules tend to be most stable when the two atoms forming a bond share enough electrons to completely occupy the outermost energy level or shell. The outermost shell of a hydrogen atom can hold two electrons; by comparison, this shell can hold eight electrons in carbon, nitrogen, and oxygen atoms. This simple rule for forming stable molecules is known as the octet rule and applies to many, but not all, elements. For example, as shown in [Fig. 2.6](#), one carbon atom (C, with four valence electrons) combines with four hydrogen atoms (H, with one valence electron each) to form  $\text{CH}_4$  (methane); nitrogen (N, with five valence electrons) combines with three H atoms to form  $\text{NH}_3$  (ammonia); and oxygen (O, with six valence electrons) combines with two H atoms to form  $\text{H}_2\text{O}$  (water). Interestingly, the elements of the same column in the next row behave similarly. This is just one example of the recurring, or periodic, behavior of the elements.

## A polar covalent bond is characterized by unequal sharing of electrons.

In hydrogen gas ( $\text{H}_2$ ), the electrons are shared equally by the two

hydrogen atoms. In many bonds, however, the electrons are not shared equally by the two atoms. A notable example is the bonds in a water molecule ( $\text{H}_2\text{O}$ ): it consists of two hydrogen atoms, each of which covalently bound to a single oxygen atom ([Fig. 2.7](#)).

FIG. 2.7 A polar covalent bond. In a polar covalent bond, the two atoms do not share the electrons equally.

In a molecule of water, the electrons are more likely to be located near the oxygen atom. The unequal sharing of electrons results from a difference in the ability of the atoms to attract electrons, a property known as [electronegativity](#). Electronegativity tends to increase across a row in the periodic table; as the number of positively charged protons across a row increases, negatively charged electrons are held more tightly to the nucleus. Therefore, oxygen is more electronegative than hydrogen and attracts electrons more readily than does hydrogen. In a molecule of water, oxygen has a slight negative charge, while the two hydrogen atoms have a slight positive charge ([Fig. 2.7](#)). When electrons are shared unequally between the two atoms, the resulting

interaction is described as a **polar covalent bond**.

A covalent bond between atoms that have the same, or nearly the same, electronegativity is described as a **nonpolar covalent bond**, which means that the atoms share the bonding electron pair almost equally. Nonpolar covalent bonds include those in gaseous hydrogen ( $\text{H}_2$ ) and oxygen ( $\text{O}_2$ ), as well as carbon–carbon ( $\text{C—C}$ ) and carbon–hydrogen ( $\text{C—H}$ ) bonds. Molecules held together by nonpolar covalent bonds are important in cells because they do not mix well with water.

## An ionic bond forms between oppositely charged ions.

In a molecule of water, the difference in electronegativity between the oxygen and hydrogen atoms leads to unequal sharing of electrons. In more extreme cases, when an atom of very high electronegativity is paired with an atom of very low electronegativity, the difference in electronegativity is so great that the electronegative atom “steals” the electron from its less electronegative partner. In this case, the atom with the extra electron has a negative charge and is a negative ion. The atom that has lost an electron has a positive charge and is a positive ion. The two ions are not covalently bound, but because opposite charges attract, they associate with each other in an **ionic bond**. An example of a compound formed by the attraction of a positive ion and a negative ion is sodium chloride ( $\text{NaCl}$ ), commonly known as table salt (**Fig. 2.8a**).

FIG. 2.8 An ionic bond. (a) Sodium chloride (salt) is formed by the attraction of two ions. (b) In solution, the ions are surrounded by water molecules.

When sodium chloride is placed in water, the salt dissolves to form sodium ions (written as “ $\text{Na}^+$ ”) that have lost an electron and so are positively charged, and chloride ions ( $\text{Cl}^-$ ) that have gained an electron and so are negatively charged. In solution, the two ions are pulled apart and become surrounded by water molecules. The negatively charged ends of water molecules are attracted to the positively charged sodium ion, and the positively charged ends of other water molecules are attracted to the negatively charged chloride ion (**Fig. 2.8b**). Only as the water evaporates do the concentrations of  $\text{Na}^+$  and  $\text{Cl}^-$  increase to the point where the ions join and precipitate as salt crystals.

## A chemical reaction involves breaking

## and forming chemical bonds.

The chemical bonds that link atoms in molecules can change in a **chemical reaction**, a process by which atoms or molecules, called **reactants**, are transformed into different molecules, called **products**.

During a chemical reaction, atoms keep their identity but change which atoms they are bonded to.

For example, two molecules of hydrogen gas ( $2\text{H}_2$ ) and one molecule of oxygen gas ( $\text{O}_2$ ) can react to form two molecules of water ( $2\text{H}_2\text{O}$ ), as shown in **Fig. 2.9**. In this reaction, the numbers of each type of atom are conserved, but their arrangement is different in the reactants and the products. Specifically, the **H—H** bond in hydrogen gas and the **O=O** bond in oxygen are broken. At the same time, each oxygen atom forms new covalent bonds with two hydrogen atoms, forming two molecules of water. In fact, this reaction is the origin of the word “hydrogen,” which literally means “water former.” The reaction releases a good deal of energy and is used in some rockets as a booster in satellite launches.

identity, but their connections change as bonds are broken and new bonds are formed.

In biological systems, chemical reactions provide a way to build and break down molecules for use by the cell, as well as to harness energy, which can be held in chemical bonds ([Chapter 6](#)).

#### Self-Assessment Questions

4. From their positions in the periodic table (see [Fig. 2.3](#)), can you predict how many lithium atoms and hydrogen atoms can combine to form a molecule?
5. What are the differences between covalent bonds and polar covalent, hydrogen, and ionic bonds?

## 2.3 WATER

On Earth, all life depends on water. Indeed, life originated in water, and the availability of water strongly influences the environmental distributions of different species. Furthermore, water is the single most abundant molecule in cells, so water is the medium in which the molecules of life interact. So important to life is water that, in the late 1990s, the National Aeronautics and Space Administration (NASA) announced that the search for extraterrestrial life would be based on a simple strategy: follow the water. NASA's logic makes sense because, within our own solar system, Earth stands out both for its abundance of water and for the life that water supports. In addition, as we saw in [Case 1 Life's Origins](#), life might even have been present on ancient Mars when liquid water was still plentiful. What makes water so special as the medium of life?

### Water is a polar molecule.

As we saw earlier, water molecules have polar covalent bonds, characterized by an uneven distribution of electrons. A molecule like water that has regions of positive and negative charge is called a [polar](#) molecule. Polar molecules tend to interact with other polar molecules, whereas nonpolar molecules tend not to interact with polar molecules. Therefore molecules, or even different regions of the same molecule, can be organized into two general classes, depending on how they interact with water: [hydrophilic](#) (“water loving”) and [hydrophobic](#) (“water fearing”).

Hydrophilic compounds are polar; they dissolve readily in water.

That is, water is a good [solvent](#), capable of dissolving many substances. Think of what happens when you stir a teaspoon of sugar into water: the sugar seems to disappear as it dissolves. The sugar molecules disperse through the water and separate from one another, forming a solution in the watery, or [aqueous](#), environment.

By contrast, hydrophobic compounds are [nonpolar](#). Nonpolar compounds do not have regions of positive and negative charge, so they arrange themselves to minimize their contact with water. For example, oil molecules are hydrophobic. Thus, when oil and water are mixed, the oil molecules organize themselves into droplets that limit the oil–water interface. This [hydrophobic effect](#), in which polar molecules like water exclude nonpolar ones, drives such biological processes as the folding of proteins ([Chapter 4](#)) and the formation of cell membranes ([Chapter 5](#)).

## A hydrogen bond is an interaction between a hydrogen atom and an electronegative atom.

Because the oxygen and hydrogen atoms have slight charges, water molecules orient themselves to minimize the repulsion of like charges so that positive charges are near negative charges. For example, because of its slight positive charge, a hydrogen atom in a water molecule tends to orient itself toward the slightly negatively charged oxygen atom in another molecule.

A [hydrogen bond](#) is the name given to this interaction between a

hydrogen atom with a slight positive charge and an electronegative atom of another molecule. In fact, any hydrogen atom covalently bound to an electronegative atom (such as oxygen or nitrogen) will have a slight positive charge and can form a hydrogen bond. In the case of water, the result of many such interactions is a molecular network stabilized by hydrogen bonds. Typically, a hydrogen bond is depicted by a dotted line, as in [Fig. 2.10](#).

Hydrogen bonds are much weaker than covalent bonds, but it is hydrogen bonding that gives water many interesting properties, described next. In addition, the presence of many weak hydrogen bonds can help stabilize biological molecules, as in the case of nucleic acids and proteins.

## Hydrogen bonds give water many

## unusual properties.

Hydrogen bonds influence the structure of both liquid water ([Fig. 2.11a](#)) and ice ([Fig. 2.11b](#)). When water freezes, most water molecules become hydrogen bonded to four other water molecules, forming an open crystalline structure we call ice. As the temperature increases and the ice melts, some of the hydrogen bonds are destabilized and break, allowing the water molecules to pack more closely and explaining why liquid water is denser than ice. As a result, ice floats on water, and ponds and lakes freeze from the top down and so do not freeze completely. This property allows fish and aquatic plants to survive winter in the cold water under the layer of ice.

FIG. 2.11 Liquid water and ice. Hydrogen bonds create (a) a dense structure in water and (b) a highly ordered, less dense, crystalline structure in ice.

Hydrogen bonds also give water molecules the property of [cohesion](#), meaning that they tend to stick to one another. A consequence of cohesion is high surface tension, a measure of the difficulty of breaking the surface of a liquid. Cohesion between

molecules contributes to water movement in plants. As water evaporates from leaves, water is pulled upward through the plant's vessels. Sometimes this water may rise as high as 100 meters above the ground in giant sequoia and coast redwood trees, which are among the tallest trees on Earth.

The hydrogen bonds of water also influence how water responds to heating. Molecules are in constant motion, and this motion increases as the temperature increases. When water is heated, some of the energy added by heating is used to break hydrogen bonds instead of causing more motion among the molecules. As a consequence, the temperature increases less in these situations than if there were no hydrogen bonding. The abundant hydrogen bonds make water more resistant to temperature changes than other substances, a property that is important for living organisms on a variety of scales. In the cell, water resists temperature variations that would otherwise result from numerous biochemical reactions. On a global scale, the oceans minimize temperature fluctuations, stabilizing the temperature on Earth in a range compatible with life.

In short, water is clearly the medium of life on Earth. But does it fill this critical role because water is uniquely suited for life, or is it because life on Earth has adapted through time to a watery environment? We don't know the answer to this question, but probably both explanations are partly true. Chemists have proposed that under conditions of high pressure and temperature, other small molecules, including ammonia ( $\text{NH}_3$ ) and some simple carbon-containing molecules, might display similar characteristics friendly to life.

However, under the conditions that exist on Earth, water is the only molecule uniquely suited to life. Water is a truly remarkable substance, and life on Earth would not be possible without it.

## pH is a measure of the concentration of protons in solution.

In any solution of water, a small proportion of the water molecules exist as protons ( $\text{H}^+$ ) and hydroxide ions ( $\text{OH}^-$ ). The pH of a solution measures the proton concentration ( $[\text{H}^+]$ ), which is important because the pH influences many chemical reactions and biological processes. It is calculated by the following formula:

$$\text{pH} = -\log[\text{H}^+]$$

The pH of a solution can range from 0 to 14. Since the pH scale is logarithmic, a difference of one pH unit corresponds to a tenfold difference in hydrogen ion concentration. A solution is neutral ( $\text{pH} = 7$ ) when the concentrations of protons ( $\text{H}^+$ ) and hydroxide ions ( $\text{OH}^-$ ) are equal. When the concentration of protons is higher than that of hydroxide ions, the pH is lower than 7 and the solution is **acidic**. When the concentration of protons is lower than that of hydroxide ions, the pH is higher than 7 and the solution is **basic**. In turn, an acid can be described as a molecule that releases a proton ( $\text{H}^+$ ), and a base is a molecule that accepts a proton in aqueous solution.

Pure water has a pH of 7—that is, it is neutral, with an equal concentration of protons and hydroxide ions. The pH of most cells is approximately 7 and is tightly regulated, as most chemical reactions

can be carried out only in a narrow pH range. Certain cellular compartments, however, have a much lower pH. The pH of blood is slightly basic, with a pH around 7.4. This value is sometimes referred to in medicine as physiological pH. Freshwater lakes, ponds, and rivers tend to be slightly acidic because carbon dioxide from the air dissolves in the water and forms carbonic acid ([Chapter 6](#)).

#### Self-Assessment Questions

6. Why do containers of water, milk, soda, or other liquids sometimes burst when frozen?
7. What are three unusual properties of water, and why do these properties make water conducive to life?

## 2.4 CARBON

Hydrogen and helium are far and away the most abundant elements in the universe. In contrast, the solid Earth is dominated by silicon, oxygen, aluminum, iron, and calcium ([Chapter 1](#)). In other words, Earth is not a typical sample of the universe. Nor is the cell a typical sample of the solid Earth. [Fig. 2.12](#) shows the relative abundance by mass of chemical elements present in human cells after all the water has been removed. Note that just four elements—carbon (C), oxygen (O), hydrogen (H), and nitrogen (N)—account for approximately 90% of the total dry mass, and that the most abundant element is carbon.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 2.12 Approximate proportions by dry mass of chemical elements found in human cells.

---

The elemental composition of human cells is typical of all cells. Human life, and all life as we know it, is based on carbon. Carbon molecules play such an important role in living organisms that carbon-containing molecules have a special name—they are called **organic molecules**. Carbon has the ability to combine with many other elements to form a wide variety of molecules, each specialized for the functions it carries out in the cell.

## Carbon atoms form four covalent bonds.

One of the special properties of carbon is that, in forming molecular orbitals, a carbon atom behaves as if it had four unpaired electrons. This behavior occurs because one of the electrons in the outermost spherical orbital moves into the empty dumbbell-shaped orbital (see [Fig. 2.2](#)). In this process, the single large spherical orbital and three dumbbell-shaped orbitals change shape, becoming four equivalent hybrid orbitals, each with one electron.

[Fig. 2.13](#) shows the molecular orbitals that result when one atom of carbon combines with four atoms of hydrogen to form the gas methane ( $\text{CH}_4$ ). Each of the four valence electrons of carbon shares a new molecular orbital with the electron of one of the hydrogen atoms. These bonds can rotate freely about their axis. Furthermore, because of the shape of the orbitals, the carbon atom lies at the center of a three-dimensional structure called a tetrahedron, and the four molecular orbitals point toward the four corners of this structure. The ability of carbon to form four covalent bonds, the spatial orientation of these

bonds in the form of a tetrahedron, and the ability of each bond to rotate freely all contribute in important ways to the structural diversity of carbon-based molecules.

## Carbon-based molecules are structurally and functionally diverse.

Carbon has other properties that contribute to its ability to form a diversity of molecules. For example, carbon atoms can link with other carbon atoms through covalent bonds, forming long chains. These chains can be branched, or two carbons at the ends of the chain or within the chain can link to form a ring.

Among the simplest chains is ethane, shown in [Fig. 2.14a](#). Ethane forms when two carbon atoms become connected by a covalent bond.

In this case, the orbitals of unpaired electrons in two carbon atoms form the covalent bond. Each carbon atom is also bound to three hydrogen atoms. Some more complex examples of carbon-containing molecules are shown in [Fig. 2.14b](#), as both structural formulas and in simplified form.

FIG. 2.14 Diverse carbon-containing molecules. (a) The molecule ethane contains one **C—C** bond. (b) A linear chain of carbon atoms and a ring structure that also contains oxygen contain multiple **C—C** bonds.

Two adjacent carbon atoms can also share two pairs of electrons, forming a double bond, as shown in [Fig. 2.15](#). Note that each carbon atom has exactly four covalent bonds, but in this case two are shared between adjacent carbon atoms. The double bond is shorter than a single bond and is not free to rotate, so all of the covalent bonds

formed by the carbon atoms connected by a double bond are in the same geometrical plane. As with single bonds, double bonds can be found in chains of atoms or ring structures.

While the types of atoms making up a molecule help characterize the molecule, the spatial arrangement of atoms is also important. For example, 6 carbon atoms, 13 hydrogen atoms, 2 oxygen atoms, and 1 nitrogen atom can join covalently in many different arrangements to produce molecules with different structures. Two of these many arrangements are shown in [Fig. 2.16](#). Note that some of the connections between atoms are identical in the two molecules (black) and some are different (green), even though the chemical formulas are the same ( $C_6H_{13}O_2N_1$ ). Molecules that have the same chemical formula but different structures are known as [isomers](#).

FIG. 2.16 The isomers isoleucine and leucine. Isoleucine and leucine have the same chemical formula, but their structures differ.

We have seen that carbon-containing molecules can adopt a wide range of arrangements, a versatility that helps us to understand how a limited number of elements can create an astonishing variety of molecules. We might ask whether carbon is uniquely versatile. Put another way, if we ever discover life on a distant planet, will it be based on carbon, like humans? Silicon, which is found just below carbon in the periodic table (see [Fig. 2.3](#)), is the one other element that is both reasonably abundant and characterized by four atomic orbitals with one electron each. Some scientists have speculated that silicon might provide an alternative to carbon as a chemical basis for life. However, silicon readily binds with oxygen. On Earth, nearly all of the silicon atoms found in molecules are covalently bound to oxygen. Studies of Mars and meteorites show that silicon is tightly bound to oxygen throughout our solar system, and that relationship is likely to be repeated everywhere we might explore. There are approximately 1000 different silicate minerals on Earth, but this diversity pales before the millions of known carbon-based molecules. If we ever discover life beyond Earth, very likely its chemistry will be based on carbon.

#### Self-Assessment Questions

8. What are the four most common elements in organic molecules and which common macromolecules always contain all four of these elements?
9. What features of carbon allow it to form diverse structures?

## 2.5 ORGANIC MOLECULES

Chemical processes in the cell depend on just a few classes of carbon-based molecules. **Proteins** provide structural support and act as catalysts that facilitate chemical reactions. **Nucleic acids** encode and transmit genetic information. **Carbohydrates** provide a source of energy and make up the cell wall in bacteria, plants, and algae. **Lipids** make up cell membranes, store energy, and act as signaling molecules.

These molecules are all large, consisting of hundreds or thousands of atoms, and many are **polymers**, complex molecules made up of repeated simpler units connected by covalent bonds. Proteins are polymers of **amino acids**, nucleic acids are polymers of **nucleotides**, and carbohydrates such as starch are polymers of simple **sugars**. Lipids are a bit different, as we will see, in that they are defined by a property rather than by their chemical structure. The lipid membranes that define cell boundaries consist of **fatty acids** bonded to other organic molecules.

Building macromolecules from simple, repeating units provides a means of generating an almost limitless chemical diversity. Indeed, in macromolecules, the building blocks of polymers play a role much like that of the letters in words. In written language, a change in the content or order of letters changes the meaning of the word (or renders it meaningless). For example, by reordering the letters of the word SILENT you can write LISTEN, a word with a different meaning. Similarly, rearranging the building blocks that make up macromolecules provides an important way to make a large number of diverse macromolecules whose functions differ from one to the next.

In the following sections, we focus on the building blocks of these four key molecules of life, reserving a discussion of the structure and function of the macromolecules for later chapters.

## Functional groups add chemical character to carbon chains.

The simple repeating units of polymers are often based on a nonpolar core of carbon atoms. Attached to these carbon atoms are **functional groups**, groups of one or more atoms that have particular chemical properties on their own, regardless of what they are attached to.

Among the functional groups frequently encountered in biological molecules are amine ( $=\text{NH}$ ), amino ( $-\text{NH}_2$ ), carboxyl ( $-\text{COOH}$ ), hydroxyl ( $-\text{OH}$ ), ketone ( $=\text{O}$ ), phosphate ( $-\text{O}-\text{PO}_3\text{H}_2$ ), sulfhydryl ( $-\text{SH}$ ), and methyl ( $-\text{CH}_3$ ). The nitrogen, oxygen, phosphorus, and sulfur atoms in these functional groups are more electronegative than the carbon atoms, and functional groups containing these atoms are polar. The methyl group ( $-\text{CH}_3$ ), in contrast, is nonpolar.

Because many functional groups are polar, molecules that contain these groups—molecules that would otherwise be nonpolar—become polar. As a result, these molecules become soluble in the cell's aqueous environment. In other words, they disperse in solution throughout the cell. Moreover, because many functional groups are polar, they are reactive. Notice in the following sections that the reactions joining simpler molecules into polymers usually take place between functional groups.

## Proteins are composed of amino acids.

Proteins do much of the cell's work. Some function as catalysts that accelerate the rates of chemical reactions (in which case they are called **enzymes**); others act as structural components necessary for cell shape and movement. The human body contains many thousands of distinct types of protein that perform a wide range of functions. Since proteins consist of amino acids linked covalently to form a chain, we need to examine the chemical features of amino acids to understand the diversity and versatility of proteins.

The general structure of an amino acid is shown in **Fig. 2.17a**. Each amino acid contains a central carbon atom, called the  **$\alpha$  (alpha) carbon**, covalently linked to four groups: an **amino group** ( $\text{—NH}_2$ ; blue), a **carboxyl group** ( $\text{—COOH}$ ; brown), a hydrogen atom (H), and an **R group**, or **side chain** (green), that differs from one amino acid to the next. The identity of each amino acid is determined by the structure and composition of the side chain. The side chain of the amino acid glycine is simply H, for example, and that of alanine is  $\text{CH}_3$ . In most amino acids, the  $\alpha$  carbon is covalently linked to four different groups. Glycine is the exception, since its R group is a hydrogen atom.

FIG. 2.17 Amino acids and peptide bonds. (a) An amino acid contains four groups attached to a central carbon atom. (b) In the environment of a cell, the amino group gains a proton and the carboxyl group loses a proton. (c) Peptide bonds link amino acids to form a protein.

At the pH commonly found in a cell (pH 7.4), the amino and carboxyl groups are ionized (charged) owing to interactions with the surrounding medium. The amino group gains a proton ( $\text{—NH}_3^+$ ; blue) and the carboxyl group loses a proton ( $\text{—COO}^-$ ; brown), as shown in [Fig. 2.17b](#).

Amino acids are linked in a chain to form a protein ([Fig. 2.17c](#)). The carbon atom in the carboxyl group of one amino acid is joined to the nitrogen atom in the amino group of the next by a covalent linkage

called a **peptide bond**. In [Fig. 2.17c](#), the chain of amino acids includes four amino acids, and the peptide bonds are indicated in red. The formation of a peptide bond involves the loss of a water molecule. That is, to form a **C—N** bond, the carbon atom of the carboxyl group must release an oxygen atom and the nitrogen atom of the amino group must release two hydrogen atoms. These oxygen and hydrogen atoms can then combine to form a water molecule (**H<sub>2</sub>O**). The loss of a water molecule also occurs in the linking of subunits to form polymers such as nucleic acids and complex carbohydrates.

Cellular proteins are composed of combinations of 20 different amino acids, each of which can be classified according to the chemical properties of its R group. The particular sequence, or order, in which amino acids are present in a protein determines how it folds into its three-dimensional structure. The three-dimensional structure, in turn, determines the protein's function. In [Chapter 4](#), we examine how the sequence of amino acids in a particular protein is specified and discuss how proteins fold into their three-dimensional shapes.

## Nucleic acids encode genetic information in their nucleotide sequence.

Nucleic acids are examples of informational molecules—that is, large molecules that carry information in the sequence of nucleotides that make them up. This molecular information is much like the information carried by the letters in an alphabet, but in the case of nucleic acids, the information is in chemical form.

The nucleic acid **deoxyribonucleic acid (DNA)** is the genetic material in all organisms. It is transmitted from parents to offspring, and it contains the information needed to specify the amino acid sequence of all the proteins synthesized in an organism. The nucleic acid **ribonucleic acid (RNA)** has multiple functions; it is a key player in protein synthesis and the regulation of gene expression.

DNA and RNA are long molecules consisting of nucleotides bonded covalently one to the next. Nucleotides, in turn, are composed of three components: a 5-carbon sugar, a nitrogen-containing compound called a **base**, and one or more phosphate groups (**Fig. 2.18**). The sugar in RNA is ribose, and the sugar in DNA is deoxyribose. The sugars differ in that ribose has a hydroxyl (OH) group on the second carbon (designated the 2 carbon), whereas deoxyribose has a hydrogen atom at this position (hence, *deoxyribose*). (By convention, the carbons in the sugar are numbered with primes—1', 2', and so on—to distinguish them from carbons in the base—1, 2, and so on.)

The bases are built from nitrogen-containing rings and are of two types. The **pyrimidine** bases ([Fig. 2.19a](#)) have a single ring and include **cytosine (C)**, **thymine (T)**, and **uracil (U)**. The **purine** bases ([Fig. 2.19b](#)) have a double-ring structure and include **guanine (G)** and **adenine (A)**. DNA contains the bases A, T, G, and C, whereas RNA contains the bases A, U, G, and C. Just as the order of amino acids provides the information carried in proteins, so, too, does the sequence of nucleotides determine the information in DNA and RNA molecules.

In DNA and RNA, each adjacent pair of nucleotides is connected by a **phosphodiester bond**, which forms when a phosphate group in one nucleotide is covalently joined to the sugar unit in another nucleotide (**Fig. 2.20**). Like the formation of a peptide bond, the formation of a phosphodiester bond involves the loss of a water molecule.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 2.20 The phosphodiester bond. Phosphodiester bonds link successive deoxyribonucleotides, forming the backbone of the DNA strand.

DNA in cells usually consists of two strands of nucleotides twisted around each other in the form of a **double helix** ([Fig. 2.21a](#)). The sugar–phosphate backbones of the strands wrap like a ribbon around the outside of the double helix, and the bases point inward. The bases form specific purine–pyrimidine pairs that are **complementary**: where one strand carries an A, the other carries a T; and where one strand carries a G, the other carries a C. Base pairing results from hydrogen bonding between the bases ([Fig. 2.21b](#)).

The genetic information in DNA is contained in the sequence, or order, in which successive nucleotides occur along the molecule. Successive nucleotides along a DNA strand can occur in *any* order, so a long molecule could contain any of an immense number of possible nucleotide sequences. This is one reason why DNA is an efficient carrier of genetic information. In [Chapter 3](#), we consider the structure and function of DNA and RNA in greater detail.

## Complex carbohydrates are made up of simple sugars.

Many of us, when we feel tired, reach for a candy bar for a quick energy boost. The energy in a candy bar comes from sugars, which are quickly broken down to release energy. Sugars belong to a class of

molecules called [carbohydrates](#), distinctive molecules composed of C, H, and O atoms, usually in the ratio 1:2:1. Carbohydrates are a major source of energy for metabolism.

The simplest carbohydrates are sugars (also called [saccharides](#)). Simple sugars are linear or, far more commonly, cyclic molecules containing five or six carbon atoms. All 6-carbon sugars have the same chemical formula ( $C_6H_{12}O_6$ ) and differ only in configuration. Glucose (the product of photosynthesis), galactose (found in dairy products), and fructose (a commercial sweetener) are examples; they share the same formula ( $C_6H_{12}O_6$ ) but differ in the arrangement of their atoms ([Fig. 2.22](#)).

FIG. 2.22 Structural formulas for some 6-carbon sugars.

A simple sugar is also called a [monosaccharide](#) (*mono* means “one”), and linking two simple sugars together by a covalent bond forms a disaccharide (*di* means “two”). Sucrose ( $C_{12}H_{22}O_{11}$ ), or table sugar, is a disaccharide that combines one molecule each of glucose and fructose. Simple sugars combine in many ways to form polymers

called **polysaccharides** (*poly* means “many”) that provide long-term energy storage (starch and glycogen) or structural support (cellulose in plant cell walls). Long, branched chains of monosaccharides are called **complex carbohydrates**.

Let’s take a closer look at monosaccharides, the simplest sugars. Monosaccharides are unbranched carbon chains with either an aldehyde ( $\text{HC=O}$ ) or a ketone ( $=\text{O}$ ), group ([Fig. 2.22](#)). Monosaccharides with an aldehyde group are called aldoses and those with a ketone group are known as ketoses. In both types of monosaccharide, the other carbons each carry one hydroxyl ( $-\text{OH}$ ) group and one hydrogen (H) atom. When the linear structure of a monosaccharide is written with the aldehyde or ketone group at the top, the carbons are numbered from top to bottom.

Almost all of the monosaccharides in cells are in ring form ([Fig. 2.23](#)), rather than linear structures. To form a ring, one end of the chain bonds to another part of the chain: the carbon in the aldehyde or ketone group forms a covalent bond with the oxygen of a hydroxyl group carried by another carbon in the same molecule. For example, cyclic glucose is formed when the oxygen atom of the hydroxyl group on carbon 5 forms a covalent bond with carbon 1, which is part of an aldehyde group. The cyclic structure is approximately flat, and you can visualize it as being perpendicular to the plane of the paper, with the covalent bonds indicated by the thick lines in the foreground of [Fig. 2.23](#). The groups attached to any carbon project either above or below the ring. When the ring is formed, the aldehyde oxygen becomes a hydroxyl group. The presence of the polar hydroxyl groups through the

sugar ring makes these molecules highly soluble in water.

Monosaccharides, especially 6-carbon sugars, are the building blocks of complex carbohydrates. Monosaccharides are attached to each other by covalent bonds called **glycosidic bonds** ([Fig. 2.24](#)). As with peptide bonds, the formation of glycosidic bonds involves the loss of a water molecule. A glycosidic bond is formed between carbon 1 of one monosaccharide and a hydroxyl group carried by a carbon atom in a different monosaccharide molecule.

Carbohydrate diversity stems in part from the monosaccharides that

make up carbohydrates, similar to the way that protein and nucleic acid diversity stems from the sequence of their subunits. Some complex carbohydrates are composed of a single type of monosaccharide, while others are a mix of different kinds of monosaccharide. Starch, for example, is a sugar storage molecule in plants composed completely of glucose molecules, whereas pectin, a component of the cell wall, contains up to five different types of monosaccharide.

## Lipids are hydrophobic molecules.

Proteins, nucleic acids, and carbohydrates all are polymers made up of smaller, repeating units with a defined structure. Lipids, however, are different. Instead of being defined by a chemical structure, they share a particular property: lipids are all hydrophobic. Because they share a property rather than a structure, lipids are a chemically diverse group of molecules. They include the familiar fats that make up part of our diet, components of cell membranes, and signaling molecules. Let's briefly consider each in turn.

**Triacylglycerol** is an example of a lipid that is used for energy storage. It is the major component of animal fat and vegetable oil. A triacylglycerol molecule is made up of three fatty acids joined to glycerol ([Fig. 2.25](#)). A **fatty acid** is a long chain of carbon atoms attached to a carboxyl group ( $\text{—COOH}$ ) at one end ([Figs. 2.25a](#) and [2.25b](#)). **Glycerol** is a 3-carbon molecule with OH groups attached to each carbon ([Fig. 2.25c](#)). The carboxyl end of each fatty acid chain attaches to glycerol at one of the OH groups ([2.25d](#)), releasing a molecule of water.

FIG. 2.25 Triacylglycerol and its components.

Fatty acids differ in the length of their hydrocarbon chain—that is, they differ in the number of carbon atoms in the chain. (A hydrocarbon is a molecule composed entirely of carbon and hydrogen atoms.) Most fatty acids in cells contain an even number of carbon atoms because they are synthesized by the stepwise addition of 2-carbon units.

Some fatty acids have one or more carbon–carbon double bonds; these double bonds can differ in number and location. Fatty acids that do not contain double bonds are described as **saturated**. Because there are no double bonds, the maximum number of hydrogen atoms is attached to each carbon atom, so all of the carbon atoms are said to be “saturated” with hydrogen atoms ([Fig. 2.25a](#)). Fatty acids that contain

carbon–carbon double bonds are **unsaturated** ([Fig. 2.25b](#)). The chains of saturated fatty acids are straight, while the chains of unsaturated fatty acids have a kink at each double bond.

Triacylglycerols can contain different types of fatty acids attached to the glycerol backbone. The hydrocarbon chains of fatty acids do not contain polar covalent bonds like those in a water molecule. Instead, their electrons are distributed uniformly over the whole molecule, so these molecules are uncharged. As a consequence, triacylglycerols are all extremely hydrophobic and, therefore, form oil droplets inside the cell. Triacylglycerols are an efficient form of energy storage because, by excluding water molecules, a large number can be packed into a small volume.

Although fatty acid molecules are uncharged, the constant motion of electrons leads to regions of slight positive and slight negative charges ([Fig. 2.26](#)). These charges, in turn, either attract or repel electrons in neighboring molecules, setting up areas of positive and negative charge in those molecules as well. The temporarily polarized molecules weakly bind to one another because of the attraction of opposite charges. These interactions are known as **van der Waals forces**. The van der Waals forces come into play only when atoms are sufficiently close to one another, and they are weaker than hydrogen bonds. Even so, many van der Waals forces acting together help to stabilize molecules.

FIG. 2.26 Van der Waals forces. Transient asymmetry in the distribution of electrons along fatty acid chains leads to asymmetry in neighboring molecules, resulting in weak attractions.

Because of van der Waals forces, the melting points of fatty acids depend on their length and level of saturation. As the length of the hydrocarbon chains increases, the number of van der Waals interactions between the chains also increases. The melting temperature increases because more energy is needed to break the greater number of van der Waals interactions. Kinks introduced by double bonds reduce the tightness of the molecular packing and, therefore, the number of intermolecular interactions. As a result, the melting temperature is lower. Thus, an unsaturated fatty acid has a

lower melting point than a saturated fatty acid of the same length. Animal fats such as butter are composed of triacylglycerols with saturated fatty acids and are solid at room temperature, whereas plant fats and fish oils are composed of triacylglycerols with unsaturated fatty acids and are liquid at room temperature.

**Steroids** such as cholesterol are a second type of lipid ([Fig. 2.27](#)). Like other steroids, cholesterol has a core composed of 20 carbon atoms bonded to form four fused rings, and it is hydrophobic. Cholesterol is a component of animal cell membranes ([Chapter 5](#)) and serves as a precursor for the synthesis of steroid hormones such as estrogen and testosterone ([Chapter 36](#)).

FIG. 2.27 The chemical structure of cholesterol.

**Phospholipids** are a third type of lipid. They are a major component of the cell membrane and are described in [Chapter 5](#).

#### Self-Assessment Questions

10. Take a close look at [Fig. 2.22](#). How is glucose different from

galactose?

11. What are essential functions of proteins, nucleic acids, carbohydrates, and lipids?
12. How is diversity achieved in polymers? Use proteins as an example.
13. What are the basic structures of amino acids, nucleotides, monosaccharides, and fatty acids? Sketch your answer.

## 2.6 LIFE'S ORIGINS

---

### CASE 1 LIFE'S ORIGINS: INFORMATION, HOMEOSTASIS, AND ENERGY

## How did the molecules of life form?

In [Chapter 1](#), we considered the similarities and differences between living and nonliving things. Four billion years ago, however, the differences may not have been so pronounced. Life originated early in our planet's history, created by a set of chemical processes that, through time, produced organisms that could be distinguished from their nonliving surroundings. How can we think scientifically about one of biology's deepest and most difficult problems? One idea is to approach life's origins experimentally, asking whether the chemical reactions likely to have taken place on the early Earth can generate the molecules of life. It is important to note that even the simplest organisms living today are far more complicated than our earliest ancestors. No one suggests that cells as we know them emerged directly from primordial chemical reactions. Rather, the quest is to discover simple molecular systems that are able to replicate themselves and are subject to natural selection.

A key starting point is the observation, introduced earlier in this chapter, that the principal macromolecules found in organisms are themselves made of simpler molecules joined together. Thus, if we want to understand how proteins might have emerged on the early

Earth, we should begin with the synthesis of amino acids, and if we are interested in nucleic acids, we should focus on nucleotides.

## The building blocks of life can be generated in the laboratory.

Research into the origins of life was catapulted into the experimental age in 1953 with an elegant experiment carried out by Stanley Miller, then a graduate student in the laboratory of Nobel laureate Harold Urey. Miller started with water vapor, methane, ammonia, and hydrogen gas—all of which are thought to have been present in the early atmosphere. He put these gases into a sealed flask and then passed a spark through the mixture ([Fig. 2.28](#)). On the primitive Earth, lightning might have supplied the energy needed to drive chemical reactions, and the spark was meant to simulate its effects. Analysis of the contents of the flask showed that a number of amino acids were generated.

### HOW DO WE KNOW?

#### FIG. 2.28

Could the building blocks of organic molecules have been generated on the early Earth?

### BACKGROUND

In the 1950s, it was widely believed that Earth's early atmosphere was rich in water vapor, methane, ammonia, and hydrogen gas, with no free oxygen.

### EXPERIMENT

Stanley Miller built an apparatus, shown here, designed to simulate

Earth's early atmosphere: a sealed flask filled with water vapor ( $\text{H}_2\text{O}$ ), methane ( $\text{CH}_4$ ), ammonia ( $\text{NH}_3$ ), and hydrogen gas ( $\text{H}_2$ ), all thought to have been present in the early atmosphere. To simulate lightning, Miller passed a spark through the mixture.

## RESULTS

As the experiment proceeded, reddish material accumulated in the flask. Analysis showed that this material included a number of amino acids, the building blocks that make up proteins, which are the key structural and functional molecules that do much of the work of the cell.

## CONCLUSION

Amino acids can be generated in conditions that mimic those of the early Earth.

## FOLLOW-UP WORK

Recent analysis of the original extracts, saved by Miller, shows that the experiment actually produced about 20 different amino acids, not all of them found in organisms.

SOURCES Miller, S. L. 1953. "Production of Amino Acids under Possible Primitive Earth Conditions." *Science* 117:528–529; Johnson, A. P., et al. 2008. "The Miller Volcanic Spark Discharge Experiment." *Science* 322:404.

Miller and others conducted many variations on his original experiment, all with similar results. Today, many scientists doubt that the early atmosphere had the composition found in Miller's experimental apparatus, but amino acids and other biologically important molecules can form in a variety of simulated atmospheric compositions. If oxygen gas ( $O_2$ ) is absent and hydrogen is more common in the mixture than carbon, the addition of energy generates diverse amino acids. The absence of oxygen gas is critical because these types of reactions cannot run to completion in modern air or seawater. Here, however, geology supports the experiments: chemical analyses of Earth's oldest sedimentary rocks indicate that, for the first 2 billion years of our planet's history, Earth's surface contained little or no oxygen.

Later experiments have shown that other chemical reactions can generate simple sugars, the bases found in nucleotides, and the lipids needed to form primitive membranes. Independent evidence that simple chemistry can form the building blocks of life comes from certain meteorites, which provide samples of the early solar system and contain diverse amino acids, lipids, and other organic molecules.

## Experiments show how life's building blocks can form macromolecules.

From the preceding discussion, we have seen that life's simple building blocks can be generated under conditions likely to have been present on the early Earth. But can these simple units be linked together to form polymers? Once again, careful experiments have shown how polymers could have formed in the conditions of the early Earth. Clay

minerals that form from volcanic rocks can bind nucleotides on their surfaces ([Fig. 2.29a](#)). The clays provide a surface that places the nucleotides near one another, making it possible for them to join to form chains or simple strands of nucleic acid.

In a classic experiment, biochemist Leslie Orgel placed a short nucleic acid sequence into a reaction vessel and then added individual chemically modified nucleotides. The nucleotides spontaneously joined into a polymer, forming the sequence complementary to the nucleic acid already present ([Fig. 2.29b](#)).

Such experiments show that nucleic acids can be synthesized experimentally from nucleotides, but until recently the synthesis of nucleotides themselves presented a formidable problem for researchers

seeking to uncover the origins of life. Many researchers tried to generate nucleotides from their sugar, base, and phosphate components, but no one succeeded until 2009. That year, John Sutherland and his colleagues showed that nucleotides can be synthesized under conditions thought to resemble those on the young Earth. These chemists showed how simple organic molecules likely to have formed in abundance on the early Earth react in the presence of phosphate molecules, yielding the long-sought nucleotides.

Such humble beginnings eventually gave rise to the abundant diversity of life we see around us, described memorably by Charles Darwin in the final paragraph of *On the Origin of Species*:

It is interesting to contemplate an entangled bank, clothed with many plants of many kinds, with birds singing on the bushes, with various insects flitting about, and with worms crawling through the damp earth, and to reflect that these elaborately constructed forms, so different from each other, and dependent on each other in so complex a manner, have all been produced by laws acting around us.... There is grandeur in this view of life ... from so simple a beginning endless forms most beautiful and most wonderful have been, and are being, evolved.

#### Self-Assessment Question

14. What evidence supports the hypothesis that life originated on Earth by the generation and polymerization of small organic molecules by natural processes?

## CORE CONCEPTS SUMMARY

**2.1 PROPERTIES OF ATOMS:** The atom is the fundamental unit of matter.

Atoms consist of positively charged protons and electrically neutral neutrons in the nucleus, as well as negatively charged electrons moving around the nucleus. [page 29](#)

The number of protons determines the identity of an atom. [page 29](#)

The number of protons and neutrons together determines the mass of an atom. [page 29](#)

The number of protons versus the number of electrons determines the charge of an atom. [page 30](#)

Negatively charged electrons travel around the nucleus in regions called orbitals. [page 30](#)

The periodic table of the elements reflects a regular and repeating pattern in the chemical behavior of elements. [page 31](#)

**2.2 MOLECULES AND CHEMICAL BONDS:** Atoms can combine to form molecules linked by chemical bonds.

Valence electrons occupy the outermost energy level (shell) of an atom and determine the ability of an atom to combine with other atoms to form molecules. [page 32](#)

A covalent bond results from the sharing of electrons between atoms to form a molecular orbital. [page 32](#)

A polar covalent bond results when two atoms do not share electrons equally as a result of a difference in the ability of the atoms to attract electrons, a property called electronegativity. [page 33](#)

An ionic bond results from the attraction of oppositely charged ions. [page 33](#)

### **2.3 WATER:** Water is abundant and essential for life.

Water is a polar molecule because shared electrons are distributed asymmetrically between the oxygen and hydrogen atoms. [page 35](#)

Hydrophilic molecules dissolve readily in water, whereas hydrophobic molecules in water tend to associate with one another, minimizing their contact with water. [page 35](#)

A hydrogen bond results when a hydrogen atom covalently bonded to an electronegative atom interacts with an electronegative atom of another molecule. [page 35](#)

Water forms hydrogen bonds, which help explain its high cohesion, surface tension, and resistance to rapid temperature change. [page 36](#)

The pH of an aqueous solution is a measure of the acidity of the solution. [page 36](#)

### **2.4 CARBON:** Carbon is the backbone of organic molecules.

A carbon atom can form up to four covalent bonds with other atoms. [page 37](#)

The geometry of these covalent bonds helps explain the structural

and functional diversity of organic molecules. [page 38](#)

**2.5 ORGANIC MOLECULES:** Organic molecules include proteins, nucleic acids, carbohydrates, and lipids, each of which is built from simpler units.

Amino acids are linked by covalent bonds to form proteins. [page 39](#)

An amino acid consists of a carbon atom (the  $\alpha$  carbon) attached to a carboxyl group, an amino group, a hydrogen atom, and a side chain. [page 39](#)

The side chain determines the properties of an amino acid. [page 40](#)

Nucleotides assemble to form nucleic acids, which store and transmit genetic information. [page 40](#)

Nucleotides are composed of a 5-carbon sugar, a nitrogen-containing base, and a phosphate group. [page 40](#)

Nucleotides in DNA incorporate the sugar deoxyribose, and nucleotides in RNA incorporate the sugar ribose. [page 40](#)

The bases are pyrimidines (cytosine, thymine, and uracil) and purines (guanine and adenine). [page 40](#)

Sugars are carbohydrates, molecules composed of C, H, and O atoms, usually in the ratio 1:2:1, and are a source of energy. [page 41](#)

Monosaccharides assemble to form disaccharides or longer polymers called complex carbohydrates. [page 42](#)

Lipids are hydrophobic. [page 43](#)

Triacylglycerols store energy and are made up of glycerol and fatty acids. [page 43](#)

Fatty acids consist of a linear hydrocarbon chain of variable length with a carboxyl group at one end. [page 43](#)

Fatty acids are either saturated (no carbon–carbon double bonds) or unsaturated (one or more carbon–carbon double bonds). [page 44](#)

The tight packing of fatty acids in lipids is the result of van der Waals forces, a type of weak, noncovalent bond. [page 44](#)

**2.6 LIFE’S ORIGINS:** Life likely originated on Earth by a set of chemical reactions that gave rise to the molecules of life.

In 1953, Stanley Miller and Harold Urey demonstrated that amino acids can be generated in the laboratory in conditions that mimic those found on the early Earth. [page 45](#)

Other experiments have shown that sugars, bases, and lipids can be generated in the laboratory. [page 45](#)

Once the building blocks were synthesized, they could join together in the presence of clay minerals to form polymers. [page 47](#)

## CHAPTER 3 Nucleic Acids and Transcription

Pasieka/Science Source

---

### CORE CONCEPTS

### 3.1 CHEMICAL COMPOSITION AND STRUCTURE OF DNA:

DNA is a polymer of nucleotides that forms a double helix.

**3.2 DNA STRUCTURE AND FUNCTION:** The structure of DNA allows it to store and transmit information.

**3.3 TRANSCRIPTION:** Genetic information is retrieved by transcription, the process by which RNA is synthesized from a DNA template.

**3.4 RNA PROCESSING:** The primary transcript is processed to become messenger RNA.

---

So much in biology depends on shape. Take your hand, for example. You can pick up a pin, text on a smartphone, or touch your pinky to your thumb. These activities are made possible by the coordinated movement of dozens of bones, muscles, nerves, and blood vessels that give your hand its shape. The functional abilities of your hand emerge from its structure. A close connection between structure and function exists in many molecules, too. Proteins are a good example. Composed of long, linear strings of 20 different kinds of amino acids in various combinations, each protein folds into a specific three-dimensional shape due to chemical interactions between the amino acids along the chain. The three-dimensional structure of the protein determines its functional properties and enables the protein to carry out its job in the cell.

Another notable example of the relationship between structure and function is the macromolecule [deoxyribonucleic acid \(DNA\)](#), a linear polymer of four different subunits. DNA molecules from all cells and organisms have a very similar three-dimensional structure, reflecting

their shared ancestry. This structure, called a [double helix](#), is composed of two strands coiled around each other to form a molecule that resembles a spiral staircase. The banisters of the spiral staircase are formed by the linear backbone of the paired strands, and the steps are formed by the pairing of the subunits at the same level in each strand.

The spiral-staircase structure is common to all cellular DNA molecules, and its structure gave clues to its function. First, DNA stores [genetic information](#) that is encoded in the sequence of subunits along its length, much as textual information is encoded in the sequence of letters along this sentence. Some of the information in DNA encodes proteins that provide structure and do much of the work of the cell. Genetic information in DNA is organized in the form of [genes](#), as textual information is organized in the form of words. Genes can exist in different forms in different individuals, even within a single species. Differences in genes can affect the shape of the hand, for example, yielding long or short fingers, or extra or missing fingers. As we will see, it is the linear order of individual subunits (bases) of DNA that accounts for differences in genes. Genes usually have no effect on the organism unless they are “turned on” and their product is made. The turning on of a gene is called [gene expression](#). The molecular processes that control whether gene expression occurs at a given time, in a given cell, or at what level are collectively called [gene regulation](#).

Second, DNA *transmits* genetic information to other molecules and from one generation to the next. The transmission of genetic information from parents to their offspring enables species of

organisms to maintain their identity through time. The genetic information in DNA guides the development of the offspring, ensuring that parental apple trees give rise to apple seedlings and parental geese give rise to goslings. As we will see, determining the double-helical structure of DNA provided one of the first hints of how genetic information could be faithfully copied from cell to cell, and from one generation to the next.

In this chapter, we examine the structure of DNA in more detail and show how its structure is well suited to its function as the carrier and transmitter of genetic information.

## 3.1 CHEMICAL COMPOSITION AND STRUCTURE OF DNA

DNA is the molecule by which hereditary information is transmitted from generation to generation. Today the role of DNA is well known, but at one time hardly any biologist would have bet on it. Any poll of biologists before about 1950 would have shown overwhelming support for the idea that proteins are life's information molecules. Compared with the seemingly monotonous, featureless structure of DNA, the three-dimensional structures of proteins are highly diverse. Proteins carry out most of the essential activities in a cell, so it seemed logical to assume that they would play a key role in heredity, too. But while proteins do play a role in heredity, they do so by supporting replication, error correction, and readout of the information encoded in DNA.

The first hint that DNA might be the genetic material came in 1928, when Frederick Griffiths conducted studies on the transmission of genetic information and showed that macromolecules in extracts from bacteria could transmit genetic information from one bacterial cell to another ([Fig. 3.1](#)). Almost 20 years later, experiments carried out by Oswald Avery, Colin MacLeod, and Maclyn McCarty showed that this information-carrying macromolecule is DNA, rather than RNA or protein ([Fig. 3.2](#)).

HOW DO WE KNOW?

FIG. 3.1

Can genetic information be transmitted between

## two strains of bacteria?

### BACKGROUND

In the 1920s, it was not clear which biological molecule carries genetic information. Fred Neufeld, a German microbiologist, identified several strains of the bacterium *Streptococcus pneumoniae*, which causes pneumonia in mice. One of these strains is virulent and causes death when injected into mice ([Fig. 3.1a](#)). A second strain is nonvirulent and does not cause illness when injected into mice ([Fig. 3.1b](#)).

### EXPERIMENT

In 1928, Frederick Griffith, another microbiologist who was also interested in bacterial virulence, made a puzzling observation. He noted that live nonvirulent bacteria, when injected into mice, do not cause mice to get sick ([Fig. 3.1b](#)). He also noted that dead virulent bacteria, when injected into mice, do not cause mice to get sick ([Fig. 3.1c](#)). However when Griffith mixed live nonvirulent bacteria and dead virulent bacteria and injected the mice with this mixture, they became sick and died ([Fig.](#)

[3.1d](#)). Furthermore, when Griffith isolated bacteria from the dead mice, the isolated bacteria appeared to be virulent, even though the mice had been injected with live nonvirulent bacteria.

## RESULTS

## CONCLUSION

Griffith concluded that the virulent bacteria, although dead, had somehow caused the nonvirulent bacteria to become virulent. He asserted that a molecule that is present in the debris of dead virulent bacteria carries the genetic information for virulence, but he did not identify the molecule. He based this conclusion on the observation that one strain of bacteria (nonvirulent) was transformed into another (virulent) by an unknown molecule from the virulent cells.

## FOLLOW-UP WORK

Griffith's experiments were followed up by many researchers, most notably Oswald Avery, Colin MacLeod, and Maclyn McCarty, who

identified DNA as the molecule responsible for transforming the bacteria from a nonvirulent strain to a virulent strain ([Fig. 3.2](#)).

SOURCE Griffith, F. 1928. "The Significance of Pneumococcal Types." *Journal of Hygiene* 27:113–159.

## HOW DO WE KNOW?

### FIG. 3.2

## Which molecule carries genetic information?

### BACKGROUND

Following Frederick Griffith, researchers Oswald Avery, Colin MacLeod, and Maclyn McCarty also studied virulence in pneumococcal bacteria. In the early 1940s, they recognized the significance of Griffith's experiments (see [Fig. 3.1](#)) and set out to identify the molecule that is responsible for transforming nonvirulent bacterial cells into virulent bacterial cells.

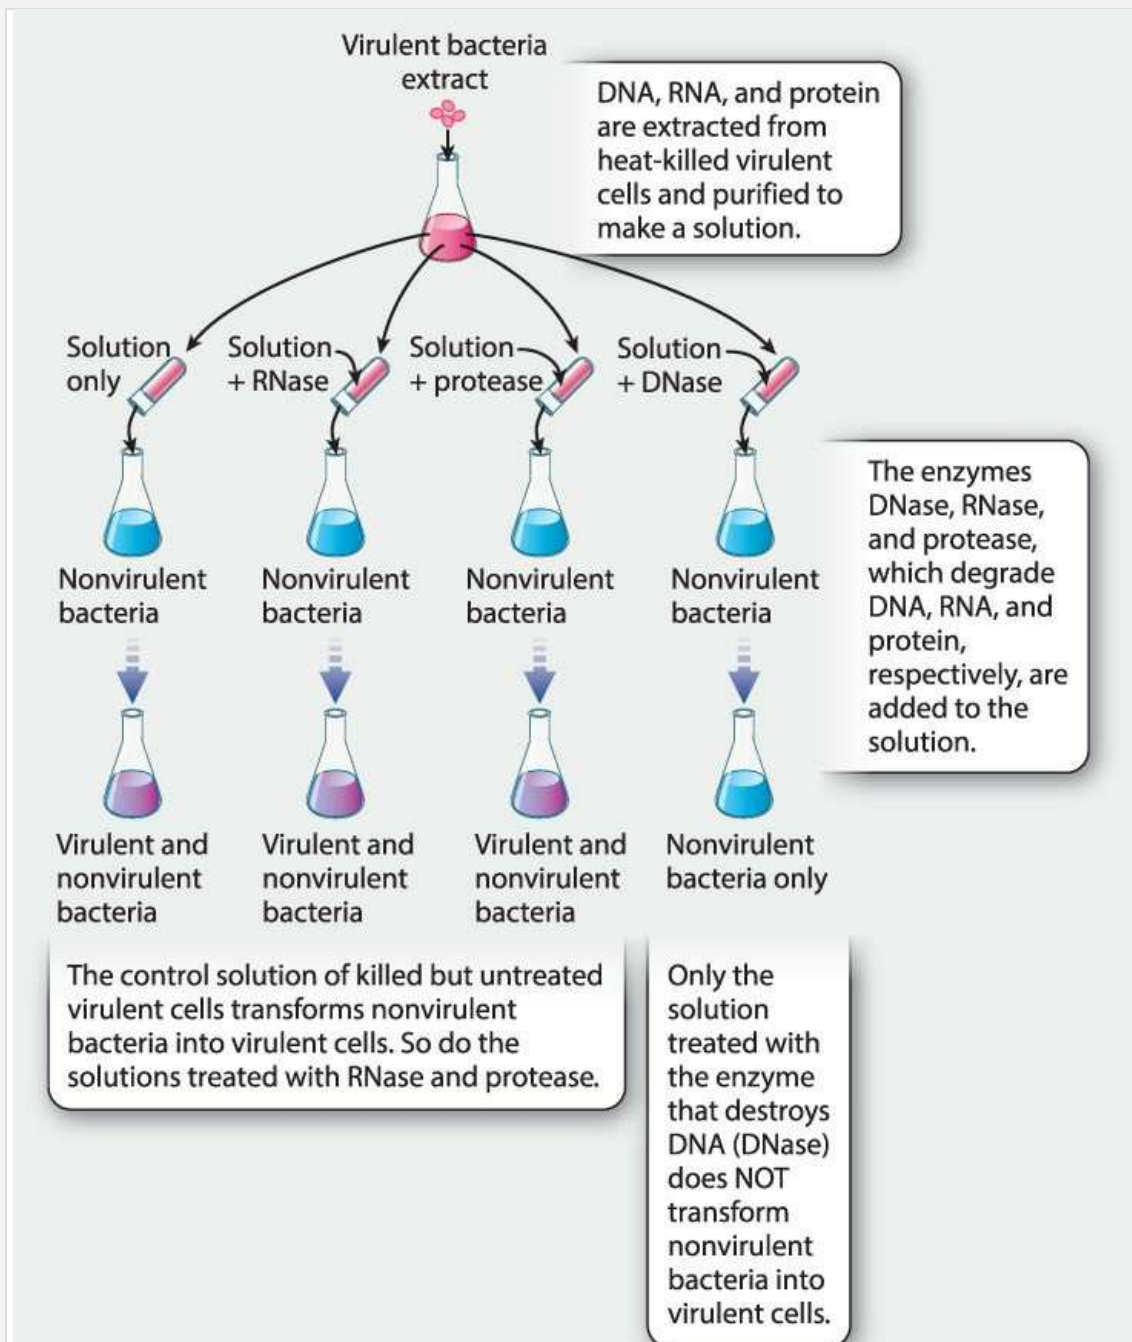

### EXPERIMENT

Avery, MacLeod, and McCarty killed virulent bacterial cells with heat, and then purified the remains of the dead virulent cells to make a solution. In their control experiment, they found that this solution of dead virulent cells did indeed transform nonvirulent bacteria into virulent ones. To identify what caused the transformation, they treated the solution with three different enzymes. Each enzyme (DNase, RNase, and protease) destroyed one of the three types of molecules (DNA, RNA, and protein) that they believed might be responsible for transformation. Their hypothesis was that transformation would not occur if the molecule responsible for transformation was destroyed by the enzymes.

### RESULTS

When the researchers treated the solution of dead virulent cells with

enzymes that destroy RNA (RNase) or protein (protease), the solution was still able to transform nonvirulent bacteria into virulent cells. In contrast, when the solution was treated with the enzyme that destroys DNA (DNase), the extract was not able to transform nonvirulent bacteria into virulent cells. In other words, the solution was no longer lethal to the mice after it was treated with DNase.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## CONCLUSION

DNA is the molecule responsible for transforming nonvirulent bacteria into virulent bacteria. This experiment provided a key piece of evidence for the idea that DNA is the genetic material.

## FOLLOW-UP WORK

These experiments were followed up by Alfred Hershey and Martha Chase, who used a different system to confirm that DNA is the genetic material.

SOURCE Avery, O., C. MacLeod, and M. McCarty. 1944. "Studies on the Chemical Nature of the Substance Inducing Transformation of Pneumococcal Types." *Journal of Experimental Medicine* 79:137–158.

To serve as the genetic material, DNA would have to be able to store genetic information, make copies of itself, and direct the synthesis of other macromolecules in the cell. How could one molecule do all this? Part of the answer emerged when James D. Watson and Francis H. C. Crick of Cambridge University announced a description of the three-dimensional structure of DNA. This discovery marked a turning point in modern biology, as the structure of DNA revealed a great deal about its function.

## A DNA strand consists of subunits called nucleotides.

In the time since the publication of Watson and Crick's paper, we have all become familiar with the iconic double helix of DNA. The elegant shape of the twisting strands relies on the structure of DNA's subunits, called **nucleotides**. As we saw in [Chapter 2](#), nucleotides consist of three components: a 5-carbon **sugar**, a **base**, and one or more

**phosphate groups (Fig. 3.3).** Each component plays an important role in DNA structure. The 5-carbon sugars and phosphate groups form the backbone of the molecule, with each sugar being linked to the phosphate group of the neighboring nucleotide. The bases sticking out from the sugar give each nucleotide its chemical identity. Each strand of DNA consists of an enormous number of nucleotides linked one to the next.

DNA had been discovered 85 years before its three-dimensional structure was determined, and in the meantime a great deal had been learned about its chemistry, specifically, the chemistry of nucleotides. In the nucleotide illustrated in [Fig. 3.3](#), the 5-carbon sugar is indicated by the pentagon, in which four of the five vertices represent the position of a carbon atom. By convention, the carbon atoms of the sugar ring are numbered clockwise with primes (1', 2', and so forth, read as “one prime,” “two prime,” and so forth). Technically, the sugar in DNA is 2'-deoxyribose (literally “minus oxygen”) because the chemical group projecting downward from the 2' carbon is a hydrogen atom (—H) rather than a hydroxyl group (—OH). For our purposes, however, the term **deoxyribose** will suffice.

Note in [Fig. 3.3](#) that the phosphate group attached to the 5' carbon has negative charges on two of its oxygen atoms. These charges are present because at cellular pH (around 7), the free hydroxyl groups attached to the phosphorus atom are ionized by the loss of a proton and, therefore, are negatively charged. It is these negative charges that make DNA a mild acid, which you will recall from [Chapter 2](#) is a molecule that tends to lose protons to the aqueous environment.

Each base is attached to the 1' carbon of the sugar and projects above the sugar ring. A nucleotide normally contains one of four kinds of bases, denoted A, G, T, and C ([Fig. 3.4](#)). Two of the bases are double-ring structures known as [purines](#); these are the bases [adenine \(A\)](#) and [guanine \(G\)](#), shown across the top of the figure. The other two bases are single-ring structures known as [pyrimidines](#); these are the bases [thymine \(T\)](#) and [cytosine \(C\)](#), shown across the bottom.

The combination of sugar and base is known as a **nucleoside**, which is shown in simplified form in **Fig. 3.5**. A nucleoside with one or more phosphate groups is termed a nucleotide. More specifically, a nucleotide with one, two, or three phosphate groups is called a nucleoside monophosphate, diphosphate, or triphosphate, respectively (**Fig. 3.5**). The nucleoside triphosphates are particularly important because, as we will see later in this chapter, they are the molecules that are used to form DNA and RNA. In addition, nucleoside triphosphates have other functions in the cell, notably as carriers of chemical energy in the form of ATP and GTP.

**DNA is a linear polymer of nucleotides linked by phosphodiester**

## bonds.

Not only were the nucleotide building blocks of DNA known before the structure was discovered, but it was also known how they were linked into a long chain or polymer. The chemical linkages between nucleotides in DNA are shown in [Fig. 3.6](#). The characteristic covalent bond that connects one nucleotide to the next is indicated by the vertical red lines that connect the 3' carbon of one nucleotide to the 5' carbon of the next nucleotide in line through the 5'-phosphate group. This  $\text{C—O—P—O—C}$  linkage is known as a [phosphodiester bond](#). In DNA, it is a relatively stable bond that can withstand stresses such as heat and substantial changes in pH that would break weaker bonds. The succession of phosphodiester bonds traces the backbone of the DNA strand.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 3.6 Nucleotides linked by phosphodiester bonds to form a DNA strand.

The phosphodiester linkages in a DNA strand give it **polarity**, which means that one end differs from the other. In [Fig. 3.6](#), the nucleotide at the top has a free 5' phosphate, and is known as the **5' end** of the molecule. The nucleotide at the bottom has a free 3' hydroxyl and is known as the **3' end**. The DNA strand in [Fig. 3.6](#) has

the sequence of bases AGCT from top to bottom, but because of strand polarity we need to specify which end is which. For this strand of DNA, we could say that the base sequence is 5'-AGCT-3' or, equivalently, 3'-TCGA-5'. When a base sequence is stated without specifying the 5' end, by convention the end at the left is the 5' end. Therefore, we can also say the sequence in [Fig. 3.6](#) is AGCT, which means 5'-AGCT-3'.

## Cellular DNA molecules take the form of a double helix.

With the knowledge of the chemical makeup of the nucleotides and their linkages in a DNA strand, Watson and Crick set out to build a molecular model of the structure of DNA. To do this, they combined three critical pieces of information. The first consisted of results from X-ray crystallography of DNA carried out by Rosalind Franklin and Maurice Wilkins, also at Cambridge University. Franklin's results were the most clear in indicating the likelihood that DNA had some sort of helical structure with a simple repeating structure all along its length, but they were incomplete and did not contain enough information for crystallographers to build models of the molecule.

The second piece of information consisted of published results of Erwin Chargaff, a biochemist at Columbia University. Chargaff had shown that DNA extracted from cells of a wide variety of organisms all have a characteristic feature: the number of molecules of the nucleotide base adenine (A) always equals the number of molecules of thymine (T), and the number of molecules of guanine (G) always equals the number of molecules of cytosine (C). This is true even though the

relative amounts of A and G vary widely from one organism to the next.

The third piece of information came from Jerry Donohue and John Griffith, colleagues of Watson and Crick at Cambridge University. They determined that, if the bases were to pair in some way, the most likely way would be that A paired with T and that G paired with C.

An accurate model of DNA would have to account for the results of all previous chemical and physical experiments. Watson and Crick went to work, using sheet metal cutouts of the bases and wire ties for the sugar–phosphate backbone. After many false starts, they finally found a structure that worked: a double-helical structure with the backbones on the outside, the bases pointing inward, and A paired with T and G paired with C.

The pair realized immediately that they had made one of the most important discoveries in all of biology. That day, February 28, 1953, they lunched at the Eagle, a pub across the street from their laboratory, where Crick loudly pronounced, “We have discovered the secret of life.” The Eagle is still there in Cambridge, England, and sports on its wall a commemorative plaque marking the table where the two ate. Watson and Crick published the structure of DNA in 1953. Knowing the structure of DNA opened the door to understanding how genetic information is stored, faithfully replicated, and able to direct the synthesis of other macromolecules. For this discovery, Watson, Crick, and Wilkins were awarded the Nobel Prize in Physiology or Medicine.

The Watson–Crick structure is shown in [Fig. 3.7](#). [Fig. 3.7a](#) is a

space-filling model, in which each atom is represented as a color-coded sphere. The big surprise of the structure is that it consists of two DNA strands like those in [Fig. 3.6](#), each wrapped around the other in the form of a helix coiling to the right, with the sugar–phosphate backbones winding around the outside of the molecule and the bases pointing inward. In the double helix, there are 10 base pairs per complete turn, and the diameter of the molecule is 2 nm. This measurement is hard to relate to everyday objects, but it might help to know that the cross section of a bundle of 100,000 DNA molecules would be about the size of the period at the end of this sentence. The outside contours of the twisted strands form an uneven pair of grooves, called the [major groove](#) and the [minor groove](#). These grooves are important because proteins that interact with DNA often recognize a particular sequence of bases by making contact with the bases by the major or minor groove or both.

FIG. 3.7 Structure of DNA. The DNA double helix can be shown with (a) the atoms as solid spheres or (b) the backbones as ribbons.

Importantly, the individual DNA strands in the double helix are **antiparallel**, which means that they run in opposite directions. That is, the 3' end of one strand is opposite the 5' end of the other. In [Fig. 3.7a](#), the strand that starts at the bottom left and coils upward begins with the 3' end and terminates at the top with the 5' end. Its partner strand begins with its 5' end at the bottom and terminates with the 3' end at the top.

[Fig. 3.7b](#) shows a different depiction of double-stranded DNA,

called a ribbon model, in which the sugar–phosphate backbones wind around the outside with the bases paired between the strands. The ribbon model of the structure closely resembles a spiral staircase, with the backbones forming the banisters and the base pairs the steps. If the amount of DNA in a human egg or sperm (3 billion base pairs) were scaled to the size of a real spiral staircase, it would reach from the Earth to the moon.

As shown in [Fig. 3.7b](#), an A in one strand pairs only with a T in the other strand, and G pairs only with C. Each base pair contains a purine and a pyrimidine. The pairing of A with T and of G with C nicely explains Chargaff’s observations, now called Chargaff’s rule. This precise pairing maintains the structure of the double helix. In contrast, pairing two purines would cause the backbones to bulge and pairing two pyrimidines would cause them to narrow, putting excessive strain on the covalent bonds in the sugar–phosphate backbone. The pairing of one purine with one pyrimidine preserves the distance between the backbones along the length of the entire molecule.

Because they form specific pairs, the bases A and T are said to be [complementary](#), as are the bases G and C. The formation of only A—T and G—C base pairs means that the paired strands in a double-stranded DNA molecule have different base sequences. The strands are paired like this:

Where one strand has the base A, the other strand across the way has

the base T. Likewise, where one strand has a G, the other has a C. In other words, the paired strands are not identical but complementary. Because of the **A—T** and **G—C** base pairing, knowing the base sequence in one strand tells you the base sequence in its partner strand.

Why is it that A pairs only with T, and G only with C? **Fig. 3.8** illustrates the answer. The specificity of base pairing is brought about by hydrogen bonds that form between A and T (two hydrogen bonds) and between G and C (three hydrogen bonds). A hydrogen bond in DNA is formed when an electronegative atom (O or N) in one base shares a hydrogen atom (H) with another electronegative atom in the base across the way. Hydrogen bonds are relatively weak bonds, typically 5% to 10% of the strength of covalent bonds, and can be disrupted by high pH or heat. However, added together, millions of these weak bonds along the molecule contribute to the stability of the DNA double helix.

FIG. 3.8 Base pairing. Adenine (A) pairs with thymine (T), and guanine (G) pairs with cytosine (C). These base pairs differ in the number of hydrogen bonds.

An almost equally important factor contributing to the stability of the double helix is the interactions between bases in the same strand (**Fig. 3.9**). This stabilizing force, known as **base stacking**, occurs because the nonpolar, flat surfaces of the bases tend to group together away from water molecules, and hence stack on top of one another as tightly as possible.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 3.9 Interactions stabilizing the double helix. Hydrogen bonds between the bases in opposite strands and base stacking of bases within a strand contribute to the stability of the DNA double helix.

#### Self-Assessment Questions

1. What are three key structural features of DNA?
2. The letter R is conventionally used to represent any purine base (A or G) and Y to represent any pyrimidine base (T or C). In

double-stranded DNA, what is the relation between the number of molecules of R and the number of molecules of Y?

## 3.2 DNA STRUCTURE AND FUNCTION

The double helix is a good example of how chemical structure and biological function come together. The structure of the molecule itself suggested how genetic information is stored in DNA—in the linear order or sequence of the base pairs. One of the most important features of DNA structure is that there is no restriction on the sequence of bases along a DNA strand. Any A, for example, can be followed by another A or by T, C, or G. The lack of sequence constraint suggested that the genetic information in DNA could be encoded in the sequence of bases along the DNA. With any of four possible bases at each nucleotide site, the information-carrying capacity of a DNA molecule is unimaginable. The number of possible base sequences of a DNA molecule only 133 nucleotides in length is equal to the estimated number of electrons, protons, and neutrons in the entire universe! This is how DNA can carry the genetic information for so many different types of organisms, and how variation in DNA sequence even within a single species can underlie genetic differences among individuals.

In addition, the structure of DNA gave important hints about other functions of DNA. For example, the base pairing of A with T and of G with C suggests how DNA is copied (replicated), as we discuss next.

**DNA molecules are copied in the process of replication, which relies on base pairing.**

DNA can serve as the genetic material because it is unique among cellular molecules in being able to specify exact copies of itself, a process known as [replication](#). Faithful replication is critical because it enables DNA to pass genetic information from cell to cell and from parent to offspring.

Even to those seeing Watson and Crick's double-helix model for the first time, the complementary, double-stranded nature of the double helix suggests a mechanism by which DNA replication takes place. In their paper on the structure of DNA, Watson and Crick noted with dry wit, "It has not escaped our notice that the specific pairing we have postulated immediately suggests a possible copying mechanism for the genetic material."

A simplified diagram of DNA replication is shown in [Fig. 3.10](#). The two strands of a parental double helix unwind and separate into single strands. As they do, each of the parental strands serves as a template, or pattern, for the synthesis of a complementary daughter strand. When the process is complete, there are two molecules, each containing one parental strand and one daughter strand, and each of which is identical in sequence to the original molecule, except possibly for rare errors that cause one base pair to be replaced with another. The sequence of bases along either strand determines that of the other because wherever one strand carries an A, the other must carry a T, and wherever one carries a G, the other must carry a C.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 3.10 DNA replication. The structure of the double helix gave an important clue to how it replicates.

Reproducing the sequence of nucleotides as precisely as possible is important because, as we will see in [Chapter 14](#), mistakes that go unrepaired may be harmful to the cell or organism. An unrepaired error in DNA replication results in a [mutation](#), which is a change in the genetic information in DNA. A mutation in DNA causes the genetic difference between virulent and nonvirulent *Streptococcus pneumoniae*, as discussed in [Fig. 3.1](#). While most mutations in genes are harmful, rare favorable mutations are essential in the process of evolution because they allow populations of organisms to change through time and adapt to their environment.

The molecular details of DNA replication are discussed in [Chapter 12](#) in the context of cell division and inheritance, two processes that fundamentally depend on DNA replication. Here, we focus on how genetic information stored in DNA is used to make RNA and proteins.

# RNA is an intermediary between DNA and protein.

Biologists often say that genetic information in DNA dictates the activities in a cell or guides the development of an organism, but these effects of DNA are actually indirect. Most of the active molecules in cells and developmental processes are proteins, including the enzymes that convert energy into usable forms and the proteins that provide structural support for the cell. The genetic information in DNA is contained in the sequence of A's, T's, G's, and C's along its length. In a protein-coding gene, DNA acts indirectly by specifying the sequence of amino acid subunits of which each protein is composed, and this sequence in turn determines the three-dimensional structure of the protein, its chemical properties, and its biological activities ([Chapter 4](#)).

To specify the amino acid sequence of proteins, DNA acts through an intermediary molecule known as [ribonucleic acid \(RNA\)](#), another type of nucleic acid. As we saw in [Chapter 1](#), the usual flow of genetic information in a cell is from DNA to RNA to protein, which has come to be known as the [central dogma](#) of molecular biology ([Fig. 3.11](#)).

The first step in decoding DNA is **transcription**, in which the genetic information in a molecule of DNA is used as a template to generate a molecule of RNA. Base pairing between a strand of DNA and RNA means that the information stored in DNA is transferred to RNA. The term “transcription” is used because it emphasizes that the information is copied from DNA to RNA in the same language of nucleic acids. Transcription is the first step in gene expression, which is the production of a functional gene product. The second step in the readout of genetic information is **translation**, in which a molecule of RNA is used as a code for the sequence of amino acids in a protein. The term “translation” is used to indicate a change of languages, from nucleotides that make up nucleic acids to amino acids that make up

proteins.

Through the years, some exceptions to the usual flow from DNA to RNA to protein have been discovered, including the transfer of genetic information from RNA to DNA (as in the human immunodeficiency virus [HIV], which causes acquired immune deficiency syndrome [AIDS]) and from RNA to RNA (as in replication of the genetic material of influenza virus). Nevertheless, in most cases the flow of information is from DNA to RNA to protein.

The processes of transcription and translation are regulated, meaning that they do not occur at all times in all cells, even though all cells in an individual contain the same DNA ([Chapter 18](#)). Genes are expressed, or “turned on,” only at certain times and places, and not expressed, or “turned off,” at other times and places. In multicellular organisms, for instance, cells are specialized for certain functions, and these different functions depend on which genes are on and which genes are off in specific cells. Muscle cells express genes that encode for proteins involved in muscle contraction, but these genes are not expressed in skin cells or liver cells, for example. Similarly, during development of a multicellular organism, genes may be required at certain times but not at others. In this case, the timing of expression is carefully controlled.

The flow of genetic information from DNA to RNA to protein applies to both prokaryotes and eukaryotes, but the differences in cell structure between the two groups mean the details of the processes differ. In prokaryotes, transcription and translation occur in the

cytoplasm. In contrast, in eukaryotes, the two processes are spatially separated from each other, with transcription occurring in the nucleus and translation in the cytoplasm. The separation of transcription and translation in time and space in eukaryotic cells allows for additional levels of gene regulation that are not possible in prokaryotic cells. In spite of this and other differences in the details of transcription and translation between prokaryotes and eukaryotes, the processes are sufficiently similar that they must have evolved early in the history of life.

#### Self-Assessment Questions

3. How does the sequence of a molecule of DNA, made up of many monomers of only four nucleotides, encode the enormous amount of genetic information stored in the chromosomes of living organisms?
4. How are the parental strands in a DNA molecule used in DNA replication?
5. What is the usual flow of genetic information in a cell?

## 3.3 TRANSCRIPTION

Although the three-dimensional structure of DNA gave important clues about how DNA stores and transmits information, it left open many questions about how the genetic information in DNA is read out to control cellular processes. In 1953, when the double helix was discovered, almost nothing was known about these processes. Within a few years, however, an accumulating body of evidence began to show that DNA carries the genetic information for proteins, and that proteins are synthesized on particles called [ribosomes](#). But in eukaryotes, DNA is located in the nucleus and ribosomes are located in the cytoplasm. Thus, there must be an intermediary molecule by which the genetic information is transferred from the DNA in the nucleus to ribosomes in the cytoplasm, and some researchers began to suspect that this intermediary was RNA.

The hypothesis of an RNA intermediary that carries genetic information from DNA to the ribosomes was supported by a clever experiment carried out in 1961 by Sydney Brenner, François Jacob, and Matthew Meselson. They used the virus T2, which infects cells of the bacterium *Escherichia coli* and hijacks the cellular machinery to produce its own viral proteins. The researchers found that while T2 DNA never associates with bacterial ribosomes, the bacteria infected with viruses produce a burst of RNA molecules shortly after infection and before they make viral proteins. This finding and others suggested that ribosomes do not synthesize proteins directly from DNA, but rather that RNA transmits the genetic information stored in DNA for use in protein synthesis. The transfer of genetic information from DNA

to RNA constitutes the key process of transcription, which we examine more closely in this section.

## RNA is a polymer of nucleotides in which the 5-carbon sugar is ribose.

RNA is a polymer of nucleotides linked by phosphodiester bonds, similar to DNA. Each RNA strand therefore has a polarity determined by which end of the chain carries the 3' hydroxyl group ( $\text{—OH}$ ) and which end carries the 5' phosphate group. A number of important differences distinguish RNA from DNA, however (**Fig. 3.12**). First, the sugar in RNA is **ribose**, which carries a hydroxyl group on the 2' carbon (highlighted in pink in **Fig. 3.12a**). Hydroxyls are reactive functional groups, so the additional hydroxyl group on ribose in part explains why RNA is a less stable molecule than DNA. Second, the base **uracil (U)** in RNA replaces thymine in DNA (**Fig. 3.12b**). The groups that participate in hydrogen bonding are identical, so that uracil pairs with adenine in RNA ( $\text{U—A}$ ) just as thymine pairs with adenine in DNA ( $\text{T—A}$ ). Third, while the 5' end of a DNA strand is typically a monophosphate, the 5' end of an RNA molecule is typically a triphosphate.

FIG. 3.12 RNA. RNA differs from DNA in that (a) RNA contains the sugar ribose rather than deoxyribose and (b) the base uracil (U) rather than thymine (T).

Two other features that distinguish RNA from DNA are physical rather than chemical. First, RNA molecules are usually much shorter than DNA molecules. A typical RNA molecule used in protein synthesis consists of a few thousand nucleotides, whereas a typical DNA molecule consists of millions or tens of millions of nucleotides. Second, most RNA molecules in the cell are single stranded, whereas DNA molecules, as we saw, are double stranded. Although RNA molecules are synthesized as single stranded, they can fold into complex, three-dimensional structures containing one or more double-stranded regions where the RNA pairs with itself. Folded RNA structures can have a three-dimensional complexity rivaling that of

proteins, and some can even serve as catalysts in biochemical reactions.

---

## CASE 1 LIFE'S ORIGINS: INFORMATION, HOMEOSTASIS, AND ENERGY

### What kinds of nucleic acids were present in the earliest cells?

RNA is a remarkable molecule. Like DNA, it can store information in its sequence of nucleotides. In addition, some RNA molecules can actually act as enzymes that facilitate chemical reactions. Because RNA has properties of both DNA (information storage) and proteins (enzymes), many scientists think that RNA, not DNA, was the original information-storage molecule in the earliest forms of life on Earth. This idea, sometimes called the [RNA world hypothesis](#), is supported by other evidence as well. Notably, as we will see, RNA is involved in key cellular processes, including DNA replication, transcription, and translation. Many scientists believe that this involvement is a remnant of a time when RNA played a more central role in life's fundamental processes.

Ingenious experiments carried out by Jack W. Szostak and collaborators show how RNA could have evolved the ability to catalyze a simple reaction. These researchers synthesized a strand of RNA in the laboratory and then replicated it many times to produce a large population of identical RNA molecules. Next, they exposed the

RNA to a chemical that induced random changes in the identity of some of the nucleotides in these molecules. These random changes were mutations that created a population of diverse RNA molecules, much in the way that mutation builds genetic variation in cells.

Next, the researchers placed all of these RNA molecules into a tube, and those RNA variants that successfully catalyzed a simple reaction—cleaving a strand of RNA, for example, or joining two strands together—were isolated, and the cycle was repeated. In each round of the experiment, the RNA molecules that functioned best were retained, replicated, subjected to treatments that induced additional mutations, and then tested for the ability to catalyze the same reaction. With each generation, the RNA catalyzed the reaction more efficiently, and after only a few dozen rounds of the procedure, very efficient RNA catalysts had evolved. Experiments such as this one suggest that RNA molecules can evolve over time and act as catalysts. Therefore, many scientists believe that RNA, with its dual functions of information storage and catalysis, was a key molecule in the very first forms of life.

If RNA played a key role in the origin of life, why do cells now use DNA for information storage and proteins to carry out other cellular processes? RNA is much less stable than DNA, and proteins are more versatile, so a plausible explanation is that life evolved from an RNA-based world to one in which DNA, RNA, and proteins are specialized for different functions.

**In transcription, DNA is used as a template to make complementary**

# RNA.

Conceptually, the process of transcription is straightforward. As a region of the DNA duplex unwinds, one strand is used as a template for the synthesis of an **RNA transcript** that is complementary in sequence to the template according to the base-pairing rules, except that the transcript contains U (uracil) where the template contains A (adenine) (**Fig. 3.13**). The transcript is produced by polymerization of ribonucleoside triphosphates. The enzyme that carries out the polymerization is known as **RNA polymerase**, which acts by adding successive nucleotides to the 3' end of the growing transcript (**Fig. 3.13**). Only the template strand of DNA is transcribed. Its partner, called the **nontemplate strand**, is not transcribed.

Although transcription is conceptually simple, in practice it takes place in stages. The first stage is **initiation**, in which RNA polymerase and other proteins are attracted to double-stranded DNA, the DNA strands are separated, and transcription of the template strand actually begins. The second stage is **elongation**, in which successive

nucleotides are added to the 3' end of the growing RNA transcript as the RNA polymerase proceeds along the template strand. The third stage is **termination**, in which the RNA polymerase encounters a sequence in the template strand that causes transcription to stop and the RNA transcript to be released.

It is important to keep in mind the direction of growth of the RNA transcript and the direction that the DNA template is read. All nucleic acids are synthesized by addition of nucleotides to the 3' end. That is, they grow in a 5'-to-3' direction, also described simply as the 3' direction. Just like the two strands of DNA in a double helix, the DNA template and the RNA strand transcribed from it are antiparallel, meaning the DNA template runs in the opposite direction from the RNA (**Fig. 3.13**). This means that, as the RNA transcript is synthesized in the 5'-to-3' direction, the DNA template is read in the opposite direction (3'-to-5').

## Transcription starts at a promoter and ends at a terminator.

A long DNA molecule typically contains thousands of genes, most of them coding for proteins or RNA molecules with specialized functions, and hence thousands of different transcripts are produced. For example, the DNA molecule in the bacterium *E. coli* has about 4.6 million base pairs and produces RNA transcripts for about 4300 proteins. A typical map of a small part of a long DNA molecule is shown in **Fig. 3.14**. Each dark green segment indicates the position where transcription is initiated, and each dark purple segment indicates the position where it ends.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 3.14 Transcription along a stretch of DNA. A DNA molecule usually contains many genes that are transcribed individually and at different times, often from opposite strands.

The green segments are **promoters**, regions of typically a few hundred base pairs where RNA polymerase and associated proteins bind to the DNA duplex. Although the term “promoter” refers to a region in double-stranded DNA because both strands are needed to recruit these proteins, transcription is initiated on only one strand. In many eukaryotic and archaeal promoters, the promoter sequence in the nontemplate strand includes 5'-TATAAA-3' or something similar, which is known as a **TATA box** because of the sequence 5'-TATA-3' (Fig. 3.14). Transcription takes place using the opposite strand as the template strand, usually starting about 25 nucleotides from the 3' end of the complement to the TATA box, and elongation occurs as the RNA polymerase moves along the template strand in the 3'-to-5' direction.

Transcription continues until the RNA polymerase encounters a sequence known as a **terminator** (dark purple in Fig. 3.14). Transcription stops at the terminator, and the transcript is released. A

long DNA molecule contains the genetic information for hundreds or thousands of genes. For any one gene, usually only one DNA strand is transcribed; however, different genes in the same double-stranded DNA molecule can be transcribed from opposite strands. Which strand is transcribed depends on the orientation of the promoter. When the promoters are in opposite orientation ([Fig. 3.14](#)), transcription occurs in opposite directions because, as noted earlier, transcription can proceed only by successive addition of nucleotides to the 3' end of the transcript.

Transcription does not take place indiscriminately from promoters, but rather is a regulated process. For the so-called housekeeping genes, whose products are needed at all times in all cells, transcription takes place continually. Most genes, however, are transcribed only at certain times, under certain conditions, or in certain cell types. In *E. coli*, for example, the genes that encode proteins needed to utilize the sugar lactose (milk sugar) are transcribed only when lactose is present in the environment. For such genes, regulation of transcription often depends on whether the RNA polymerase and associated proteins are able to bind with the promoter ([Chapter 18](#)).

In bacteria, promoter recognition is mediated by a protein called [sigma factor](#), which associates with RNA polymerase and facilitates its binding to specific promoters. Sigma binding is transient. Once transcription is initiated, the sigma factor dissociates and the RNA polymerase continues transcription on its own. One type of sigma factor is used for transcription of housekeeping genes and many others, but there are other sigma factors for genes whose expression is needed

under special environmental conditions such as lack of nutrients or excess heat.

Promoter recognition in eukaryotes is considerably more complicated. Transcription requires the combined action of at least six proteins known as **general transcription factors** that assemble at the promoter of a gene. Assembly of the general transcription factors is necessary for transcription to occur, but not sufficient. Also needed is the presence of one or more types of **transcriptional activator protein**, each of which binds to a specific DNA sequence known as an **enhancer** (**Fig. 3.15**). Transcriptional activator proteins help control when and in which cells transcription of a gene will occur. They are able to bind with enhancer DNA sequences as well as with proteins that allow transcription to begin. As a consequence, the presence of the transcriptional activator proteins that bind with enhancers controlling the expression of the gene is required for transcription of any eukaryotic gene to begin (**Fig. 3.15**).

FIG. 3.15 The eukaryotic transcription complex, composed of many different proteins.

Once transcriptional activator proteins have bound to enhancer DNA sequences, they can attract, or recruit, a **mediator complex** of proteins, which in turn recruits the RNA polymerase complex to the promoter. Because enhancers can be located almost anywhere, sometimes far from the gene, the recruitment of the mediator complex and the RNA polymerase complex may require the DNA to loop around as shown in [Fig. 3.15](#). Cells have several different types of RNA polymerase enzymes, but in both prokaryotes and eukaryotes all protein-coding genes are transcribed by just one of them. In eukaryotes, the RNA polymerase complex responsible for transcription of protein-coding genes is called **Pol II**. Once the mediator complex

and Pol II complex are in place, transcription is initiated.

## RNA polymerase adds successive nucleotides to the 3' end of the transcript.

Once transcriptional initiation takes place, successive ribonucleotides are added to grow the transcript in the process of elongation.

Transcription takes place in a sort of bubble in which the strands of the DNA duplex are separated and the growing end of the RNA transcript is paired with the template strand, creating an RNA–DNA duplex ([Fig. 3.16](#)). In bacteria, the total length of the transcription bubble is about 14 base pairs, and the length of the RNA–DNA duplex in the bubble is about 8 base pairs.

Details of the polymerization reaction are shown in [Fig. 3.17](#). The incoming ribonucleoside triphosphate, shown at the bottom right, is

accepted by the RNA polymerase only if it undergoes proper base pairing with the base in the template DNA strand. In [Fig. 3.17](#), there is a proper match because U pairs with A. At this point, the RNA polymerase orients the 3' end of the growing strand so that the oxygen in the hydroxyl group can attack the innermost phosphate of the triphosphate of the incoming ribonucleoside, competing for the covalent bond. The bond connecting the innermost phosphate to the next is a high-energy phosphate bond, which when cleaved provides the energy to drive the reaction that creates the phosphodiester bond attaching the incoming nucleotide to the 3' end of the growing chain. The term “high-energy” here refers to the amount of energy released when the phosphate bond is broken; this energy can be used to drive other chemical reactions.

The polymerization reaction releases a phosphate–phosphate group (pyrophosphate), shown at the lower right in [Fig. 3.17](#), which also has

a high-energy phosphate bond that is cleaved by another enzyme. Cleavage of the pyrophosphate molecule makes the polymerization reaction irreversible, and the next ribonucleoside triphosphate that complements the template is brought into line.

## The RNA polymerase complex is a molecular machine that opens, transcribes, and closes duplex DNA.

Transcription does not take place spontaneously. It requires template DNA, a supply of ribonucleoside triphosphates, and RNA polymerase, the large multiprotein complex in which transcription occurs. To illustrate RNA polymerase in action, we consider here bacterial RNA polymerase because of its relative simplicity.

The transcription bubble forms and transcription takes place inside the polymerase (**Fig. 3.18**). RNA polymerase contains structural features that separate the DNA strands, allow an RNA–DNA duplex to form, elongate the transcript nucleotide by nucleotide, release the finished transcript, and restore the original DNA double helix. [Fig. 3.18](#) shows how structure and function come together in the bacterial RNA polymerase.

FIG. 3.18 The RNA polymerase complex in prokaryotes. This molecular machine has channels for DNA input and output, nucleotide input, and RNA output, and features that disrupt the DNA double helix, stabilize the RNA–DNA duplex, and allow the DNA double helix to re-form.

RNA polymerase is a remarkable molecular machine capable of adding thousands of nucleotides to a transcript before dissociating from the template. It is also very accurate, with fewer than 1 incorrect nucleotide incorporated per 10,000 nucleotides.

#### Self-Assessment Questions

6. What are four differences between the structure of DNA and RNA?
7. A segment of one strand of a double-stranded DNA molecule has the sequence 5'-ACTTTCAGCGAT-3'. What is the sequence of an RNA molecule synthesized from this DNA template?
8. What is the consequence for a growing RNA transcript if an

abnormal nucleotide with a 3'-H is incorporated rather than a 3'-OH? How about a 2'-H rather than a 2'-OH?

---

## 3.4 RNA PROCESSING

The RNA transcript that comes off the template DNA strand is known as the **primary transcript**, and it contains the complement of every base that was transcribed from the DNA template. For protein-coding genes, this means that the primary transcript includes the information needed to direct the ribosome to produce the protein corresponding to the gene ([Chapter 4](#)). The RNA molecule that combines with the ribosome to direct protein synthesis is known as **messenger RNA (mRNA)** because it carries the genetic “message” (information) from the DNA to the ribosome. As we will see in this section, there is a major difference between prokaryotes and eukaryotes in how the primary transcript and mRNA differ from each other. We will also see that some genes do not code for proteins, but rather for RNA molecules that have functions of their own.

### Primary transcripts in prokaryotes are translated immediately.

In prokaryotes, the relation between the primary transcript and mRNA is as simple as can be: the primary transcript *is* the mRNA. Even as the 3' end of the primary transcript is still being synthesized, ribosomes bind with special sequences near its 5' end and begin the process of protein synthesis ([Fig. 3.19](#)).

This intimate connection between transcription and translation can take place because prokaryotes have no nuclear envelope to spatially separate transcription from translation. Thus, the two processes are coupled, which means that they are connected in space and time.

Primary transcripts for protein-coding genes in prokaryotes have another feature not shared with those in eukaryotes: they often contain the genetic information for the synthesis of two or more different proteins. Usually these proteins code for successive steps in the biochemical reactions that produce small molecules needed for growth, or for successive steps needed to break down a small molecule used for nutrients or energy. Molecules of mRNA that code for multiple proteins are known as **polycistronic mRNA** because the term “cistron” was once widely used to refer to a protein-coding sequence in a gene.

## Primary transcripts in eukaryotes undergo several types of chemical modification.

In eukaryotes, the nuclear envelope is a barrier between the processes of transcription and translation. Transcription takes place in the nucleus, and translation in the cytoplasm. The separation allows for a complex chemical modification of the primary transcript, known as **RNA processing**, which converts the primary transcript into the finished mRNA, which can then be translated by the ribosome.

RNA processing consists of three principal types of chemical modifications, illustrated in **Fig. 3.20**. First, the 5' end of the primary transcript is modified by the addition of a special nucleotide attached in an unusual linkage. This addition, which is called the **5' cap**, consists of a modified nucleotide called 7-methylguanosine. An enzyme attaches the modified nucleotide to the 5' end of the primary transcript essentially backward: in a normal linkage between two nucleotides, the phosphodiester bond forms between the 3'-OH group of one nucleotide and the 5' carbon of the next nucleotide, but here the cap is linked to the RNA transcript by a triphosphate bridge between the 5' carbons of both ribose sugars (**Fig. 3.21**). The 5' cap is essential for translation because in eukaryotes, the ribosome recognizes an mRNA by its 5' cap. Without the cap, the ribosome would not attach to the mRNA and translation would not occur.

FIG. 3.20 Fate of the primary transcript for protein-coding genes in eukaryotes.

FIG. 3.21 Structure of the 5' cap in eukaryotic messenger RNA.

The second major modification of eukaryotic primary transcripts is

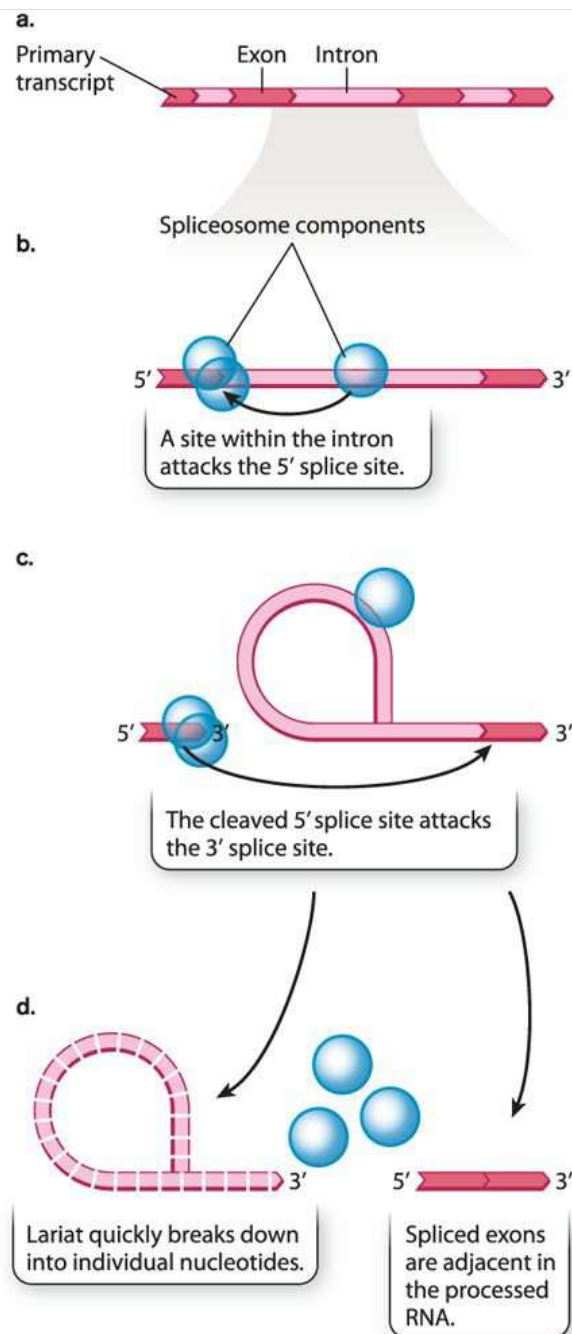

**polyadenylation**, the addition of a string of about 250 consecutive A-bearing ribonucleotides to the 3' end, forming a **poly(A) tail** (see [Fig. 3.20](#)). Polyadenylation plays an important role in the export of mRNA into the cytoplasm. In addition, both the 5' cap and the poly(A) tail help to stabilize the RNA transcript. Single-stranded nucleic acids can be unstable and are even susceptible to enzymes that break them down. In eukaryotes, the 5' cap and poly(A) tail protect the two ends of the transcript and increase the stability of the RNA transcript until it is translated in the cytoplasm.

Not every stretch of the RNA transcript ends up being translated into protein. Transcripts in eukaryotes often contain regions of protein-coding sequence, called **exons**, interspersed with noncoding regions called **introns**. The third type of modification of the primary transcript is the removal of the noncoding introns (see [Fig. 3.20](#)). The process of intron removal is known as **RNA splicing**, which is catalyzed by a complex of RNA and protein known as the **spliceosome**.

The mechanism of splicing is outlined in [Fig. 3.22](#). In the first step, the spliceosome brings a specific sequence within the intron into proximity with the 5' end of the intron, at a site known as the 5' splice site ([Fig. 3.22a](#)). The proximity enables a reaction that cuts the RNA at the 5' splice site, and the cleaved end of the intron connects back on itself, forming a loop and tail called a **lariat** ([Fig. 3.22b](#)). In the next step, the spliceosome brings the 5' splice site close to the splice site at the 3' end of the intron. The 5' splice site attacks the 3' splice site ([Fig. 3.22c](#)), cleaving the bond that holds the lariat on the transcript and attaching the ends of the exons to each other. The result is that the

exons are connected and the lariat is released (Fig. 3.22d). The lariat making up the intron is quickly broken down into its constituent nucleotides.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 3.22 RNA splicing.

The presence of introns has important implications for gene expression. Approximately 90% of all human genes contain at least one intron. Although most genes contain 6 to 9 introns, the largest number is 147 introns, found in a muscle gene. Most introns are just a few thousand nucleotides in length, but roughly 10% are longer than 10,000 nucleotides. The presence of multiple introns in most genes allows for a process known as **alternative splicing**, in which primary transcripts from the same gene can be spliced in different ways to yield different mRNAs and, therefore, different protein products (**Fig. 3.23**). More than 80% of human genes are alternatively spliced. In most cases, the alternatively spliced forms differ in whether a particular exon is or is not removed from the primary transcript along with its flanking introns. Alternative splicing allows the same transcript to be processed in diverse ways to produce mRNA molecules with different combinations of exons coding for different proteins.

FIG. 3.23 Alternative splicing. A single primary transcript can be spliced in different ways.

## Some RNA transcripts are processed differently from protein-coding transcripts and have functions of their OWN.

Not all primary transcripts are processed into mRNA. Some RNA transcripts have functions of their own, and many of these transcripts are produced by RNA polymerases other than Pol II. These primary transcripts undergo different types of RNA processing, and their processed forms include some important noncoding types of RNA:

- **Ribosomal RNA (rRNA)**, which makes up the bulk of ribosomes and is essential in translation. In eukaryotic cells, the genes and transcripts for rRNA are concentrated in the **nucleolus**, a distinct, dense, non-membrane-bound spherical structure observed within the nucleus. The structure and function of ribosomes are examined in [Chapter 4](#).
- **Transfer RNA (tRNA)**, which carries individual amino acids for use in translation. The way in which amino acids become attached to tRNA and are then transferred to a growing polypeptide chain is discussed in [Chapter 4](#).
- **Small nuclear RNA (snRNA)**, which is an essential component of the spliceosome required for RNA processing.
- Small, regulatory RNA molecules that can inhibit translation or

cause destruction of an RNA transcript. Two major types of small regulatory RNA are known as [\*\*microRNA \(miRNA\)\*\*](#) and [\*\*small interfering RNA \(siRNA\)\*\*](#). The roles of these types of RNA in gene regulation are examined in [Chapter 18](#).

By far, the most abundant transcripts in mammalian cells are those for ribosomal RNA and transfer RNA. In a typical mammalian cell, approximately 80% of the RNA consists of ribosomal RNA, and another approximately 10% consists of transfer RNA. Why are these types of RNA so abundant? The answer is that they are needed in large amounts to synthesize the proteins encoded in the messenger RNA, which is the subject of the next chapter.

#### Self-Assessment Questions

9. What are three mechanisms of RNA processing in eukaryotes?
10. What are five types of noncoding RNA and their functions?
11. When a region of DNA that contains the genetic information for a protein is isolated from a bacterial cell and inserted into a eukaryotic cell in a proper position between a promoter and a terminator, the resulting cell usually produces the correct protein. But when the experiment is done in the reverse direction (inserting eukaryotic DNA into a bacterial cell), the correct protein is often not produced. Why is this the case?

## CORE CONCEPTS SUMMARY

### 3.1 CHEMICAL COMPOSITION AND STRUCTURE OF DNA:

DNA is a polymer of nucleotides that forms a double helix.

Experiments on *Streptococcus pneumoniae* conducted by F. Griffith showed that a nonvirulent strain of bacteria could be transformed into a virulent one by some unknown substance. [page 52](#)

Experiments on pneumococcal bacteria conducted by Avery, MacLeod, and McCarty provided evidence that DNA is the genetic material. [page 52](#)

A nucleotide consists of a 5-carbon sugar, a phosphate group, and a base. [page 53](#)

The four bases of DNA are adenine (A), guanine (G), cytosine (C), and thymine (T). [page 54](#)

Successive nucleotides are linked by phosphodiester bonds to form a linear strand of DNA. [page 54](#)

DNA strands have polarity, with a 5'-phosphate group at one end and a 3'-hydroxyl group at the other end. [page 55](#)

In a DNA double helix, A pairs with T, and G pairs with C. [page 55](#)

**3.2 DNA STRUCTURE AND FUNCTION:** The structure of DNA allows it to store and transmit information.

Information is coded in the sequence of bases of DNA. [page 58](#)

DNA structure suggests a mechanism for replication, in which each parental strand serves as a template for a daughter strand. [page 58](#)

Ribonucleic acid (RNA) is synthesized from a DNA template in the process of transcription. [page 58](#)

The central dogma of molecular biology states that the usual flow of genetic information is from DNA to RNA to protein. DNA is transcribed to RNA, and RNA is translated to protein. [page 58](#)

**3.3 TRANSCRIPTION:** Genetic information is retrieved by transcription, the process by which RNA is synthesized from a DNA template.

RNA, like DNA, is a polymer of nucleotides linked by phosphodiester bonds. [page 60](#)

Unlike DNA, RNA incorporates the sugar ribose instead of deoxyribose and the base uracil instead of thymine. [page 60](#)

Some types of RNA can store genetic information, while other types can catalyze chemical reactions. These characteristics have led to the RNA world hypothesis, the idea that RNA played a critical role in the early evolution of life on Earth. [page 60](#)

RNA is synthesized from one of the two strands of DNA, called the template strand. [page 61](#)

RNA is synthesized by RNA polymerase in a 5'-to-3' direction, starting at a promoter and ending at a terminator in the DNA template. [page 61](#)

Specific DNA sequences such as enhancers, promoters, and terminators participate in transcriptional regulation. [page 62](#)

RNA polymerase separates the two DNA strands, allows an RNA–DNA duplex to form, elongates the transcript, releases the transcript, and restores the DNA duplex. [page 62](#)

**3.4 RNA PROCESSING:** The primary transcript is processed to become messenger RNA.

In prokaryotes, the primary transcript is immediately translated into protein. [page 65](#)

In eukaryotes, transcription and translation are separated in time and space, with transcription occurring in the nucleus and then translation in the cytoplasm. [page 65](#)

In eukaryotes, there are three major types of modification to the primary transcript—the addition of a 5' cap, polyadenylation, and splicing. [page 65](#)

Alternative splicing is a process in which primary transcripts from the same gene are spliced in different ways to yield different protein products. [page 66](#)

Some RNAs, called noncoding RNAs, do not code for proteins, but instead have functions of their own. [page 67](#)

## CHAPTER 4 Translation and Protein Structure

LAGUNA DESIGN/Getty Images

---

## CORE CONCEPTS

**4.1 MOLECULAR STRUCTURE OF PROTEINS:** Proteins are linear polymers of amino acids that form three-dimensional structures with specific functions.

**4.2 PROTEIN SYNTHESIS:** Translation is the process in which the sequence of bases in messenger RNA specifies the order of successive amino acids in a newly synthesized protein.

**4.3 PROTEIN ORIGINS AND EVOLUTION:** Proteins evolve through mutation and selection and by combining functional units.

---

Hardly anything happens in the life of a cell that does not require proteins. They are the most versatile of macromolecules, each with its own built-in ability to carry out a cellular function. Some proteins aggregate to form relatively stiff filaments that help define the cell's shape and hold organelles in position. Others span the cell membrane and form channels or pores through which ions and small molecules can move. Many others are enzymes that catalyze the thousands of chemical reactions needed to maintain life. Still others are signaling proteins that enable cells to coordinate their internal activities or to communicate with other cells.

Want to see some proteins? Look at the white of an egg. Apart from the 90% or so that is water, most of what you see is protein. The predominant type of protein is ovalbumin. Easy to obtain in large quantities, ovalbumin was one of the first proteins studied through scientific inquiry ([Chapter 1](#)). In the 1830s, ovalbumin was shown to

consist largely of carbon, hydrogen, nitrogen, and oxygen. Each molecule of ovalbumin was estimated to contain at least 400 carbon atoms. Leading chemists of the time scoffed at this number, believing that no organic molecule could possibly be so large. Little did they know: the number of carbon atoms in ovalbumin is actually closer to 2000 than to 400!

The reason that proteins can be such large organic molecules began to become clear only about a hundred years ago, when scientists hypothesized that proteins are polymers (large molecules made up of repeated subunits). Now we know that proteins are linear polymers of any combination of 20 amino acids, each of which differs from the other proteins in its chemical characteristics. In size, ovalbumin is actually an average protein, consisting of a chain of 385 amino acids.

In [Chapter 3](#), we discussed how genetic information flows from the sequence of bases of DNA into the sequence of bases in a transcript of RNA. For protein-coding genes, the transcript is processed into messenger RNA (mRNA). In this chapter, we examine how amino acid polymers are assembled by ribosomes by means of a template of messenger RNA and transfer RNAs. We also discuss how the amino acid sequences of proteins help determine their three-dimensional structures and diverse chemical activities, as well as how proteins change through evolutionary time.

## 4.1 MOLECULAR STRUCTURE OF PROTEINS

If you think of a protein as analogous to a word in the English language, then the amino acids are like letters. The comparison is not altogether fanciful, as there are nearly as many amino acids in proteins as there are letters in the alphabet, and the order of both amino acids and letters is important. For example, the word PROTEIN has the same letters as POINTER, but the two words have completely different meanings. Similarly, the exact order of amino acids in a protein determines the protein's shape and function.

### Amino acids differ in their side chains.

The general structure of an amino acid was discussed in [Chapter 2](#) and is shown again in [Fig. 4.1](#). It consists of a central carbon atom, called the  **$\alpha$  (alpha) carbon**, connected by covalent bonds to four different chemical groups ([Fig. 4.1a](#)): an **amino group** ( $\text{—NH}_2$ , shown in dark blue), a **carboxyl group** ( $\text{—COOH}$ , shown in brown), a hydrogen atom ( $\text{—H}$ , shown in light blue), and a variable **side chain** or **R group** (shown in green). In the environment of a cell, where the pH is in the range 7.35–7.45 (called physiological pH), the amino group gains a proton to become  $\text{—NH}_3^+$  and the carboxyl group loses a proton to become  $\text{—COO}^-$  ([Fig. 4.1b](#)). The four covalent bonds from the  $\alpha$  carbon are at equal angles. As a result, an amino acid forms a tetrahedron, a pyramid with four triangular faces ([Fig. 4.1c](#)).

FIG. 4.1 Structure of an amino acid. The central carbon atom is attached to an amino group, a carboxyl group, an R group or side chain, and a hydrogen atom.

The R groups of the amino acids differ from one amino acid to the next. They are what make the “letters” of the amino acid “alphabet” distinct from one another. Just as letters differ in their shapes and sounds—vowels like E, I, and O and consonants like B, P, and T—amino acids differ in their chemical and physical properties.

The chemical structures of the 20 amino acids commonly found in proteins are shown in [Fig. 4.2](#). The R groups (shown in green) are chemically diverse and are grouped according to their properties, with a particular emphasis on whether they are hydrophobic or hydrophilic, or have special characteristics that might affect a protein’s structure. These properties strongly influence how a polypeptide folds, and hence

affect the three-dimensional shape of the protein.

FIG. 4.2 Structures of the 20 amino acids commonly found in proteins.

Hydrophobic amino acids do not readily interact with water or form hydrogen bonds. Most hydrophobic amino acids have nonpolar R groups composed of hydrocarbon chains or uncharged carbon rings.

Because water molecules in the cell form hydrogen bonds with each other instead of with the hydrophobic R groups, the hydrophobic R groups tend to aggregate with each other. Their aggregation is also stabilized by weak van der Waals forces ([Chapter 2](#)), in which asymmetries in electron distribution create temporary charges in the interacting molecules, which are then attracted to each other. The tendency for hydrophilic water molecules to interact with each other and for hydrophobic molecules to interact with each other is the very same tendency that leads to the formation of oil droplets in water. It is also the reason why most hydrophobic amino acids tend to be buried in the interior of folded proteins, where they do not interact with water.

Amino acids with polar R groups have a permanent charge separation, in which one end of the R group is slightly more negatively charged than the other. As we saw in [Chapter 2](#), polar molecules are hydrophilic, and they tend to form hydrogen bonds with each other or with water molecules.

The R groups of the basic and acidic amino acids are typically charged and, therefore, are strongly polar. At the pH of a cell, the R groups of the basic amino acids gain a proton and become positively charged, whereas those of the acidic amino acids lose a proton and become negatively charged. Because the R groups of these amino acids are charged, they are usually located on the outside surface of the folded molecule. The charged groups can also form ionic bonds with each other and with other charged molecules in the environment, with a negatively charged group or molecule bonding with a positively charged group or molecule. This ability to bind another molecule of

opposite charge is an important way in which proteins can associate with each other or with other macromolecules such as DNA.

The properties of several amino acids are noteworthy because of their effect on protein structure. These amino acids include glycine, proline, and cysteine. Glycine is different from the other amino acids because its R group is hydrogen, exactly like the hydrogen on the other side of the  $\alpha$  carbon, and therefore the glycine molecule is not asymmetric. All of the other amino acids have four different groups attached to the  $\alpha$  carbon and are asymmetric. In addition, glycine is nonpolar and small enough to tuck into spaces where other R groups would not fit. The small size of glycine's R group also allows for freer rotation around the **C—N** bond since its R group does not get in the way of the R groups of neighboring amino acids. Thus, glycine increases the flexibility of the polypeptide backbone, which can be important in the folding of the protein.

Proline is also distinctive, but for a different reason. Note how its R group is linked back to the amino group. This linkage creates a kink or bend in the polypeptide chain and restricts rotation of the **C—N** bond, thereby imposing constraints on protein folding in its vicinity, an effect that is the very opposite of glycine's.

Cysteine makes a special contribution to protein folding through its **—SH** group. When two cysteine side chains in the same or different polypeptides come into proximity, they can react to form an **S—S** disulfide bond, which covalently joins the side chains. Such disulfide bonds are stronger than the ionic interactions of other pairs of amino

acid, and form cross-bridges that can connect different parts of the same protein or even different proteins. This property contributes to the overall structure of single proteins or combinations of proteins.

## Successive amino acids in proteins are connected by peptide bonds.

Amino acids are linked together to form proteins ([Fig. 4.3](#)). The bond formed between the two amino acids is a **peptide bond**, shown in red in [Fig. 4.3](#). In forming the peptide bond, the carboxyl group of one amino acid reacts with the amino group of the next amino acid in line, and a molecule of water is released. In the resulting molecule, the R groups of each amino acid point in different directions.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 4.3 Formation of a peptide bond. A peptide bond forms between the carboxyl group of one amino acid and the amino group of another.

The  $\text{C}=\text{O}$  group in the peptide bond is known as a carbonyl group, and the  $\text{N}-\text{H}$  group is an amide group. Note in [Fig. 4.3](#) that these two groups appear on either side of the peptide bond. The electrons of the peptide bond are more attracted to the  $\text{C}=\text{O}$  group than to the  $\text{NH}$  group because of the greater electronegativity of the oxygen atom. The result is that the peptide bond has some of the characteristics of a double bond. The peptide bond is shorter than a single bond, for example, and it is not free to rotate like a single bond. The other bonds are free to rotate around their central axes.

Polymers ranging from as few as two to many hundreds of amino acids linked together share a chemical feature common to individual amino acids: namely, the ends are chemically distinct from each other. One end, shown at the left in [Fig. 4.3](#), has a free amino group; this is the **amino end** of the molecule. The other end has a free carboxyl group; it is the **carboxyl end** of the molecule. More generally, a polymer of amino acids connected by peptide bonds is known as a **polypeptide**. Typical polypeptides produced in cells consist of a few hundred amino acids. In human cells, the shortest polypeptides are approximately 100 amino acids in length; the longest is the muscle protein titin, with 34,350 amino acids. The term **protein** is often used as a synonym for polypeptide, especially when the polypeptide chain has folded into a stable, three-dimensional conformation. Amino acids that are incorporated into a protein are often referred to as amino acid **residues**. In a polypeptide chain at physiological pH, the amino and carboxyl ends are in their charged states of  $\text{NH}_3^+$  and  $\text{COO}^-$ , respectively. However, for simplicity, we denote the ends as  $\text{NH}_2$  and  $\text{COOH}$ .

## The sequence of amino acids dictates protein folding, which determines function.

Up to this point, we have considered the sequence of amino acids that make up a protein. This is the first of several levels of protein structure, illustrated in [Fig. 4.4](#). The sequence of amino acids in a protein is its **primary structure**. The sequence of amino acids ultimately determines how a protein folds. Interactions between stretches of

amino acids in a protein form local [secondary structures](#). Longer-range interactions between these secondary structures in turn support the overall three-dimensional shape of the polypeptide, which is its [tertiary structure](#). Finally, some proteins are made up of several individual polypeptides that interact with each other, and the resulting ensemble is the [quaternary structure](#).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 4.4 Levels of protein structure. The manner in which a polypeptide folds determines its shape and function.

Proteins have remarkably diverse functions in the cell, ranging from serving as structural elements to communicating with the external environment to accelerating the rate of chemical reactions. No matter what the function of a protein is, the ability to carry out this function depends on the three-dimensional shape of the protein. When fully folded, some proteins contain pockets with positively or negatively charged side chains at just the right positions to trap small molecules; others have surfaces that can bind another protein or a sequence of nucleotides in DNA or RNA; some form rigid rods for structural support; and still others keep their hydrophobic side chains away from water molecules by inserting into the cell membrane.

The sequence of amino acids in a protein (its primary structure) is usually represented by a series of three-letter or one-letter abbreviations for the amino acids (abbreviations for the 20 common amino acids are given in [Fig. 4.2](#)). By convention, the amino acids in a protein are listed in order from left to right, starting at the amino end and proceeding to the carboxyl end. The amino and the carboxyl ends are different, so the order matters. Just as TIPS is not the same word as SPIT, the sequence Thr–Ile–Pro–Ser is not the same polypeptide as Ser–Pro–Ile–Thr.

## Secondary structures result from hydrogen bonding in the polypeptide

## backbone.

Hydrogen bonds can form between the carbonyl group in one peptide bond and the amide group in another, thus allowing localized regions of the polypeptide chain to fold. This localized folding is a major contributor to the secondary structure of the protein.

In the early 1950s, American structural biologists Linus Pauling and Robert Corey used X-ray crystallography to study the structure of proteins. In this procedure, researchers first form a crystal in which the atoms of the protein are in an ordered pattern in three dimensions, and then rotate the crystal in a beam of X-rays. Some X-rays pass through the crystal, while the atoms of the proteins scatter other X-rays in different directions. A film or other detector records the pattern of scattered X-rays as a series of spots, and the locations and intensities of these spots can be used to infer the position and arrangement of the atoms in the molecule. Pauling and Corey studied crystals of highly purified proteins and discovered that two types of secondary structure are found in many different proteins: the [α \(alpha\) helix](#) and the [β \(beta\) sheet](#). Both of these secondary structures are stabilized by hydrogen bonding along the polypeptide backbone.

In α helices, like the one shown in [Fig. 4.5](#), the polypeptide backbone is twisted tightly in a right-handed coil with 3.6 amino acids per complete turn. The helix is stabilized by hydrogen bonds that form between each amino acid's carbonyl group (C=O) and the amide group (N—H) four residues ahead in the sequence, as indicated by the dashed lines in [Fig. 4.5](#). Note that the R groups project outward from the α helix. The chemical properties of the projecting R groups largely

determine where the  $\alpha$  helix is positioned in the folded protein, and how it might interact with other molecules.

FIG. 4.5 An  $\alpha$  helix. Hydrogen bonds between carbonyl and amide groups in the backbone stabilize the helix.

The other secondary structure that Pauling and Corey found is the  $\beta$  sheet, depicted in [Fig. 4.6](#). In a  $\beta$  sheet, the polypeptide folds back and forth on itself, forming a pleated sheet that is stabilized by hydrogen bonds between carbonyl groups in one chain and amide groups in the other chain across the way (dashed lines). The R groups project alternately above and below the plane of the  $\beta$  sheet.  $\beta$  sheets typically consist of 4 to 10 polypeptide chains aligned side by side, with the

amide groups in each chain hydrogen-bonded to the carbonyl groups on either side (except for those at the ends of each strand).

The  $\beta$  sheets are typically denoted by broad arrows, where the direction of the arrow runs from the amino end of the polypeptide segment to the carboxyl end. In [Fig. 4.6](#), the arrows run in opposite directions, and the polypeptide chains are said to be antiparallel.  $\beta$  sheets can also be formed by hydrogen bonding between polypeptide chains that are parallel (pointing in the same direction). However, the antiparallel configuration is more stable because the carbonyl and amide groups are more favorably aligned for hydrogen bonding.

## Tertiary structures result from interactions between amino acid side chains.

The tertiary structure of a protein is the three-dimensional conformation of a single polypeptide chain, usually made up of several

secondary structure elements. Tertiary structure is defined largely by interactions between the amino acid R groups. By contrast, the formation of secondary structures relies on interactions in the polypeptide backbone and is relatively independent of the R groups. Tertiary structure is determined by the spatial distribution of hydrophilic and hydrophobic R groups along the molecule, as well as by different types of chemical bonds and interactions (ionic, hydrogen, and van der Waals) that form between various R groups. The amino acids whose R groups form bonds with each other may be far apart in the polypeptide chain, but can end up near each other in the folded protein. Hence, the tertiary structure usually includes loops or turns in the backbone that allow these R groups to sit near each other in space and for bonds to form.

The three-dimensional shapes of proteins can be illustrated in different ways, as shown in [Fig. 4.7](#). A ball-and-stick model ([Fig. 4.7a](#)) draws attention to the atoms in the amino acid chain. A ribbon model ([Fig. 4.7b](#)) emphasizes secondary structures, with  $\alpha$  helices depicted as twisted ribbons and  $\beta$  sheets as broad arrows. Finally, a space-filling model ([Fig. 4.7c](#)) shows the overall shape and contour of the folded protein.

FIG. 4.7 Three ways of showing the structure of the protein tubulin: (a) ball-and-

stick model; (b) ribbon model; (c) space-filling model.

Recall that the folding of a polypeptide chain is determined by the sequence of amino acids. The primary structure determines the secondary and tertiary structures. Furthermore, tertiary structure determines function because it is the three-dimensional shape of the molecule—the contours and distribution of charges on the outside of the molecule and the presence of pockets that might bind with smaller molecules on the inside—that enables the protein to serve as structural support, membrane channel, enzyme, or signaling molecule. **Fig. 4.8** shows the tertiary structure of a bacterial protein that contains a pocket in the center in which certain R groups can form hydrogen bonds with a specific small molecule and hold it in place.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

**FIG. 4.8** Tertiary structure determines function. This bacterial protein has a cavity that can bind with a small molecule (shown as a ball-and-stick model in the center).

The principle that structure determines function can be demonstrated by many observations. For example, most proteins can be unfolded, or **denatured**, by chemical treatment or high temperature that disrupts the hydrogen and ionic bonds holding the tertiary structure together. Under these conditions, the proteins lose their functional activity. Similarly, mutant proteins containing an amino acid that prevents proper folding are often inactive or do not function properly.

The first demonstration that the primary structure of a protein (its amino acid sequence) determines its folding into secondary and tertiary structures was based on studies of the enzyme ribonuclease A. In 1961, Christian Anfinsen and colleagues chemically denatured ribonuclease A and completely inactivated the enzyme. They then removed the denaturing agents and found that the enzyme completely recovered its activity (**Fig. 4.9**). These experiments demonstrated that the secondary and tertiary structures are formed by the primary sequence. For these experiments, Anfinsen was awarded a Nobel Prize in 1972.

#### HOW DO WE KNOW?

### FIG. 4.9

## What determines secondary and tertiary structure of proteins?

#### BACKGROUND

Natural selection influences the function that derives from the folded secondary and tertiary structure of a protein. However, only the primary structure (amino acid sequence) is encoded by a protein-coding gene. This seeming paradox was reconciled by the demonstration that the folded secondary and tertiary structure is determined by the primary structure.

## EXPERIMENT

Christian B. Anfinsen and his colleagues at the National Institutes of Health conducted experiments on the structure of ribonuclease A, a relatively small protein of 124 amino acids that acts as an enzyme. Anfinsen and colleagues measured the activity of ribonuclease A after treating it with various combinations of two chemicals, 2-mercaptoethanol (ME) and urea. In ribonuclease A, as in many other proteins, the sulfhydryl groups ( $\text{—SH}$ ) of pairs of cysteine residues form a covalent disulfide bond ( $\text{—S—S—}$ ) that links the cysteine side chains ([Fig. 4.9a](#)). These disulfide bonds are relatively weak covalent bonds and they break in the presence of the mild reducing agent ME. Urea forms stronger hydrogen bonds than do water molecules, and for this reason urea disrupts the hydrogen bonds that help stabilize a polypeptide chain as well as the hydrophobic core of the protein.

## RESULTS

When the researchers treated the purified ribonuclease A enzyme with a mixture of urea and ME, the enzyme completely lost activity ([Fig. 4.9a](#)). When the ME was removed and the enzyme was treated with urea only, the enzyme was misfolded and also inactive ([Fig. 4.9b](#)). However, when the urea was removed and only a trace of ME retained, the protein regained activity ([Fig. 4.9c](#)).

### INTERPRETATION

Treating the enzyme with urea and ME results in the loss of all disulfide bonds and complete unfolding of the protein ([Fig. 4.9a](#)). As a result, the enzyme loses its activity. When the ME is removed but urea retained, the protein folds in such a way that the disulfide bonds form incorrectly between the cysteine residues ([Fig. 4.9b](#)). The improper disulfide bonds result in loss of enzyme activity. When the urea is removed and only a trace of ME is retained, the trace ME allows the incorrect disulfide bonds to break and re-form with the proper partner, so that the protein folds into the correct structure, regaining its activity ([Fig. 4.9c](#)).

### CONCLUSION

These findings supported the hypothesis that the primary sequence dictates protein folding. Under normal conditions in the cell, the folding takes place spontaneously as the protein reaches a state of minimum free energy.

#### FOLLOW-UP WORK

Some proteins fold relatively slowly and require the help of other proteins called chaperones. Chaperones sequester the folding proteins so that the unfolded intermediates do not aggregate to form more complex structures. Many diseases, including Alzheimer's disease, Parkinson's disease, and mad cow disease (bovine spongiform encephalopathy), result from improperly folded protein aggregates.

SOURCE Anfinsen, C. B., Haber, E., Sela, M., and White, F. H., Jr. 1961. The kinetics of formation of native ribonuclease during oxidation of the reduced polypeptide chain. *Proceedings of the National Academy of Sciences U.S.A.* 47:1309–1314.

## Polypeptide subunits can come together to form quaternary structures.

Although many proteins are complete and fully functional as a single polypeptide chain with a tertiary structure, many other proteins are composed of two or more polypeptide chains or subunits with a tertiary structure that come together to form a higher-order quaternary structure. In the case of a multi-subunit protein, the activity of the complex depends on the quaternary structure formed by the combination of the various tertiary structures.

In a protein with quaternary structure, the polypeptide subunits may be either identical or different ([Fig. 4.10](#)). [Fig. 4.10a](#) shows an example of a protein produced by the human immunodeficiency virus (HIV) that consists of two identical polypeptide subunits. By contrast, many proteins, such as hemoglobin (shown in [Fig. 4.10b](#)), are composed of different subunits. In either case, the subunits can influence each other in subtle ways and influence their function. For example, the

hemoglobin in red blood cells that carries oxygen has four subunits. When one of these subunits binds to oxygen, a slight change in its structure is transmitted to the other subunits, making it easier for them to take up oxygen. In this way, oxygen transport from the lungs to the tissues is improved.

## Chaperones help some proteins fold properly.

The amino acid sequence (primary structure) of a protein determines how it forms its secondary, tertiary, and quaternary structures. For approximately 75% of proteins, the folding process takes place within milliseconds as the molecule is synthesized. Some proteins fold more slowly, however, and for these molecules folding is a dangerous business. The longer these polypeptides remain in a denatured (unfolded) state, the longer their hydrophobic groups are exposed to other macromolecules in the crowded cytoplasm. The hydrophobic effect, along with van der Waals interactions, tends to bring the

exposed hydrophobic groups together, and their inappropriate aggregation may prevent proper folding. Correctly folded proteins can sometimes unfold because of elevated temperature, for example, and in the denatured state they are subject to the same risks of aggregation.

Cells have evolved proteins called **chaperones** that help protect slow-folding or denatured proteins until they can attain their proper three-dimensional structure. Chaperones bind with hydrophobic groups and nonpolar R groups to shield them from inappropriate aggregation, and in repeated cycles of binding and release they give the polypeptide time to find its correct shape.

#### Self-Assessment Questions

1. Draw one of the 20 amino acids and label the amino group, the carboxyl group, the R group (side chain), and the  $\alpha$  carbon.
2. What are the three major groups of amino acids as categorized by the properties of their R groups? How do the chemical properties of each group affect protein shape?
3. How do peptide bonds, hydrogen bonds, ionic bonds, disulfide bridges, and noncovalent interactions (van der Waals forces and the hydrophobic effect) define a protein's four levels of structure?
4. What ultimately determines the three-dimensional shape of a protein?
5. A mutation leads to a change in one amino acid in a protein. The result is that the protein no longer functions properly. How is this possible?

## 4.2 PROTEIN SYNTHESIS

The three-dimensional structure of a protein determines what it can do and how it works, and the immense diversity in the tertiary and quaternary structures among proteins explains their wide range of functions in cellular processes. Yet it is the sequence of amino acids along a polypeptide chain—its primary structure—that governs how the molecule folds into a stable three-dimensional configuration. This sequence is specified by the sequence of nucleotides in the DNA, in coded form. The decoding of the information takes place according to the central dogma of molecular biology, which defines information flow in a cell from DNA to RNA to protein ([Fig. 4.11](#)). In transcription, the sequence of bases along part of a DNA strand is used as a template in the synthesis of the complementary sequence of bases in a molecule of RNA, as described in [Chapter 3](#). In **translation**, the sequence of bases in an RNA molecule known as **messenger RNA** (mRNA) is used to specify the order in which successive amino acids are added to a newly synthesized polypeptide chain.

FIG. 4.11 The central dogma, showing how information flows from DNA to RNA to protein. Note the large number of cellular components required for translation.

## Translation uses many molecules found in all cells.

Translation requires many components. More than 100 genes encode components needed for translation, some of which are shown in [Fig. 4.11](#). What are these needed components? First, the cell needs [ribosomes](#), which are complex structures of RNA and protein that bind with mRNA and are the site of translation. In prokaryotes, translation occurs as soon as the mRNA comes off the DNA template. In eukaryotes, the processes of transcription and translation are physically separated: transcription takes place in the nucleus, and translation takes place in the cytoplasm.

In both eukaryotes and prokaryotes, the ribosome consists of a small

subunit and a large subunit, each composed of 1 to 3 types of ribosomal RNA and 20 to 50 types of ribosomal protein. Eukaryotic ribosomes are larger than prokaryotic ribosomes. As indicated in [Fig. 4.12](#), the large subunit of the ribosome includes three binding sites for molecules of transfer RNA, which are called the [A \(aminoacyl\) site](#), the [P \(peptidyl\) site](#), and the [E \(exit\) site](#).

A major role of the ribosome is to ensure that, when the mRNA is in place on the ribosome, the sequence in the mRNA coding for amino acids is read in successive, non-overlapping groups of three nucleotides, much as you would read the following sentence:

THEBIGBOYSAWTHEBADMANRUN

Each non-overlapping group of three adjacent nucleotides (like THE or BIG or BOY in our sentence analogy) constitutes a [codon](#). In turn, each codon in the mRNA codes for a single amino acid in the

polypeptide chain.

In the preceding example, it is clear that the sentence begins with THE. However, in a long linear mRNA molecule, the ribosome could begin at any nucleotide. As an analogy, if we knew that the letters THE were the start of the phrase, then we would know immediately how to read

ZWTHEBIGBOYSAWTHEBADMANRUN

However, without knowing where to start reading this string of letters, we could find three ways to break the sentence into three-letter words:

ZWT HEB IGB OYS AWT HEB ADM ANR UN

Z WTH EBI GBO YSA WTH EBA DMA NRU N

ZW THE BIG BOY SAW THE BAD MAN RUN

The different ways of parsing the string into three-letter words are known as **reading frames**. The protein-coding sequence in an mRNA consists of its sequence of bases, and just as in our sentence analogy, it can be translated into the correct protein only if it is translated in the proper reading frame.

While the ribosome establishes the correct reading frame for the codons, the actual translation of each codon in the mRNA into one amino acid in the polypeptide is carried out by means of transfer RNA (tRNA). Transfer RNAs are small RNA molecules consisting of 70 to 90 nucleotides (**Fig. 4.13**). Each has a characteristic self-pairing

structure that can be drawn as a cloverleaf, as in [Fig. 4.13a](#), in which the letters indicate the bases common to all tRNA molecules. The actual structure, though, is more like that in [Fig. 4.13b](#). Three bases in the anticodon loop make up the **anticodon**; these are the three nucleotides that undergo base pairing with the corresponding codon.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 4.13 Transfer RNA structure depicted in (a) a cloverleaf configuration and (b) a more realistic three-dimensional structure.

Each tRNA has the nucleotide sequence CCA at its 3' end ([Fig. 4.13](#)), and the 3' hydroxyl of the A is the attachment site for the amino acid corresponding to the anticodon. Enzymes called [aminoacyl tRNA synthetases](#) connect specific amino acids to specific tRNA molecules ([Fig. 4.14](#)). Therefore, these enzymes are directly responsible for actually translating the codon sequence in a nucleic acid to a specific amino acid in a polypeptide chain. Most organisms have one aminoacyl tRNA synthetase for each amino acid. The enzyme binds to multiple sites on any tRNA that has an anticodon corresponding to the amino acid, and it catalyzes formation of the covalent bond between the amino acid and tRNA. A tRNA that has no amino acid attached is said to be uncharged, whereas one with its amino acid attached is said to be charged. Amino acid tRNA synthetases are very accurate and attach the wrong amino acid far less often than 1 time in 10,000.

FIG. 4.14 Function of aminoacyl tRNA synthetase enzymes. Aminoacyl tRNA synthetases attach specific amino acids to tRNAs. In this way, they are responsible for translating the codon sequence in an mRNA into an amino acid sequence in a protein.

Although the aminoacyl tRNA synthetase has the specificity necessary for attaching an amino acid to the correct tRNA, the specificity of DNA–RNA and codon–anticodon interactions result from base pairing. [Fig. 4.15](#) shows the relationships for one codon in double-stranded DNA, in the corresponding mRNA, and in the codon–anticodon pairing between the mRNA and the tRNA. Note that the first (5′) base in the codon in mRNA pairs with the last (3′) base in the anticodon because, as noted in [Chapter 3](#), nucleic acid strands that undergo base pairing must be antiparallel.

FIG. 4.15 Role of base pairing. Base pairing determines the relationship between a three-base triplet in double-stranded DNA and a codon in mRNA, and between a codon in mRNA and an anticodon in tRNA.

## The genetic code shows the correspondence between codons and amino acids.

[Fig. 4.15](#) shows how the codon AUG specifies the amino acid methionine (Met) by base pairing with the anticodon of a charged tRNA, denoted  $\text{tRNA}^{\text{Met}}$ . Most codons specify an amino acid according to a **genetic code**. This code is sometimes called the “standard” genetic code because, while it is used by almost all cells, some minor differences are found in a few organisms as well as in mitochondria.

The codon at which translation begins is called the initiation codon. It is coded by AUG, which specifies Met. The polypeptide is synthesized from the amino end to the carboxyl end, so Met forms the amino end of any polypeptide being synthesized; in many cases, however, the Met is cleaved off by an enzyme after synthesis is complete. The AUG codon also specifies the incorporation of Met at internal sites within the polypeptide chain.

As is apparent in [Fig. 4.15](#), the AUG codon that initiated translation is preceded by a region in the mRNA that is not translated. The position of the initiator AUG codon in the mRNA establishes the reading frame that determines how the downstream codons (those following the AUG) are to be read.

Once the initial Met creates the amino end of a new polypeptide chain, the downstream codons are read one by one in non-overlapping groups of three bases. At each step, the ribosome binds to a tRNA with an anticodon that can base pair with the codon, and the amino acid on that tRNA is attached to the growing chain to become the new carboxyl end of the polypeptide chain. This process continues until one of three “stop” codons is encountered: UAA, UAG, or UGA. (The stop codons are also called termination codons or sometimes nonsense codons.) At this point, the polypeptide is finished and released into the cytosol.

The standard genetic code was deciphered in the 1960s by a combination of techniques, but among the most ingenious were the chemical methods for making synthetic RNAs of known sequence developed by American biochemist Har Gobind Khorana and his colleagues. This experiment is illustrated in [Fig. 4.16](#).

#### HOW DO WE KNOW?

### FIG. 4.16

## How was the genetic code deciphered?

#### BACKGROUND

The genetic code shows the correspondence between three-letter nucleotide codons in RNA and the amino acids in a protein. American biochemist Har Gobind Khorana performed key experiments that helped to crack the code. For this work he shared the Nobel Prize in Physiology or Medicine in 1968 with Robert W. Holley and Marshall E. Nirenberg.

#### METHOD

Khorana and his group constructed synthetic RNAs with predetermined sequences. They then added these synthetic RNAs to a solution containing

all of the other components needed for translation. The researchers used laboratory conditions that allowed ribosomes to initiate synthesis with any codon, even when the codon was not AUG.

#### EXPERIMENT 1 AND RESULTS

When Khorana's group constructed an mRNA with just repeating uracils [called poly(U)], it was translated into a polyphenylalanine polypeptide (Phe–Phe–Phe...):

#### CONCLUSION

Ribosomes translate the codon UUU into the amino acid Phe. The poly(U) mRNA can be translated in three possible reading frames, depending on which U is the 5' end of the start codon. In each of those reading frames, all the codons are UUU.

#### EXPERIMENT 2 AND RESULTS

When Khorana's group synthesized an mRNA with alternating U and C ribonucleotides, the resulting polypeptide had alternating serine (Ser) and leucine (Leu):

#### CONCLUSION

Here again are three possible reading frames, but each has alternating UCU and CUC codons. The researchers could not deduce from this result whether UCU corresponds to Ser and CUC to Leu, or the other way around; the correct assignment came from experiments using other

synthetic mRNA molecules.

### EXPERIMENT 3 AND RESULTS

When Khorana's group synthesized an mRNA with repeating UCA, three different polypeptides were produced from multiple rounds of translation: polyserine (Ser), polyhistidine (His), and polyisoleucine (Ile).

### CONCLUSION

This mRNA could be read by the ribosome as repeated UCAs, repeated CAUs, or repeated AUCs, depending on which bases the ribosome read first. The results do not reveal which of the three reading frames corresponds to which amino acid, but this was sorted out by studies of other synthetic polymers.

SOURCE Khorana, H. G. 1972. "Nucleic Acid Synthesis in the Study of the Genetic Code." In *Nobel Lectures, Physiology or Medicine 1963–1970*. Amsterdam: Elsevier.

The standard genetic code shown in [Table 4.1](#) has 20 amino acids specified by 61 codons. Thus, many amino acids are specified by more than one codon, and the genetic code is redundant, or degenerate. The redundancy has strong patterns, however:

- The redundancy results almost exclusively from the third codon position.
- When an amino acid is specified by two codons, they differ either in whether the third position is a U or a C (both pyrimidine bases), or in whether the third position is an A or a G (both purine bases).
- When an amino acid is specified by four codons, the identity of the third codon position does not matter; it could be U, C, A, or G.

**TABLE 4.1 The standard genetic code.**

| First position (5' end) | Second position                                   |                                          |                                                          |                                                  | Third position (3' end) |

The chemical basis of these patterns results from two features of translation. First, in many tRNA anticodons, the 5' base that pairs with the 3' (third) base in the codon is chemically modified into a form that can pair with two or more bases at the third position in the codon.

Second, in the ribosome, there is less than perfect alignment between the third position of the codon and the base that pairs with it in the anticodon, so the requirements for base pairing are somewhat relaxed. This feature of the codon–anticodon interaction is referred to as wobble.

## Translation consists of initiation, elongation, and termination.

Translation is usually divided into three separate processes: initiation, elongation, and termination. First, in [initiation](#), the initiator AUG codon is recognized and Met is established as the first amino acid in the new polypeptide chain. Next, in [elongation](#), successive amino acids are added one by one to the growing chain. Finally, in [termination](#), the addition of amino acids stops and the completed polypeptide chain is released from the ribosome.

Initiation of translation ([Fig. 4.17](#)) requires a number of protein [initiation factors](#) that bind to the mRNA. In eukaryotes, one group of initiation factors binds to the 5' cap that is added to the mRNA during processing. These factors recruit a small subunit of the ribosome, and other initiation factors bring up a transfer RNA charged with Met ([Fig. 4.17a](#)). The initiation complex then moves along the mRNA until it encounters the first AUG triplet. The position of this AUG establishes the translational reading frame.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

**FIG. 4.17 Translational initiation and elongation.** In eukaryotes, the codon used for initiation is the AUG codon nearest the 5' end of the mRNA. Note that the growing polypeptide chain remains attached to a tRNA throughout translation.

When the first AUG codon is encountered, a large ribosomal

subunit joins the complex, the initiation factors are released, and the next tRNA is ready to join the ribosome ([Fig. 4.17b](#)). Note in [Fig. 4.17b](#) that the  $\text{tRNA}^{\text{Met}}$  binds with the P (peptidyl) site in the ribosome and that the next tRNA in line comes in at the A (aminoacyl) site. Once the new tRNA is in place, a reaction takes place in which the bond connecting the Met to its tRNA is transferred to the amino group of the next amino acid in line, forming a peptide bond between the two amino acids ([Fig. 4.17c](#)). An RNA in the large subunit is the actual catalyst for this reaction. In this way, the new polypeptide becomes attached to the tRNA in the A site. The ribosome then shifts one codon to the right ([Fig. 4.17d](#)). With this move, the uncharged  $\text{tRNA}^{\text{Met}}$  shifts to the E site and is released into the cytoplasm, and the peptide-bearing tRNA shifts to the P site. The movement of the ribosome also empties the A site, making it available for the next charged tRNA in line to come into place.

At this point, steps (d) and (e) in [Fig. 4.17](#) are repeated over and over again in the process of elongation, so that the polypeptide chain grows in length through the addition of successive amino acids. Ribosome movement along the mRNA and formation of the peptide bonds require energy, which is obtained with the help of proteins called **[elongation factors](#)**. Elongation factors are bound to GTP molecules, and break their high-energy bonds to provide energy for the elongation of the polypeptide.

The elongation process shown in [Fig. 4.17](#) continues until the ribosome encounters one of the stop codons (UAA, UAG, or UGA); these codons signal termination of polypeptide synthesis. Termination

takes place because the stop codons do not have corresponding tRNA molecules. Rather, when the ribosome encounters a stop codon, a protein **release factor** binds to its A site (**Fig. 4.18**). The release factor causes the bond connecting the polypeptide to the tRNA to break, creating the carboxyl terminus of the polypeptide and completing the chain. Once the finished polypeptide is released, the small and large ribosomal subunits disassociate both from the mRNA and from each other.

Although elongation and termination are very similar in prokaryotes and in eukaryotes, translation initiation differs between the two (**Fig. 4.19**). In eukaryotes, the initiation complex forms at the 5' cap and scans along the mRNA until the first AUG is encountered (**Fig. 4.19a**). In prokaryotes, the mRNA molecules have no 5' cap. Instead, the initiation complex is formed at one or more internal sequences present

in the mRNA known as a Shine–Dalgarno sequence ([Fig. 4.19b](#)). In *Escherichia coli*, the Shine–Dalgarno sequence is 5'-AGGAGGU-3', and it is followed by an AUG codon eight nucleotides farther downstream that serves as an initiation codon for translation. The ability to initiate translation internally allows prokaryotic mRNAs to code for more than one protein. Such an mRNA is known as a [polycistronic mRNA](#). In [Fig. 4.19b](#), the polycistronic mRNA codes for three different polypeptide chains, each with its own AUG initiation codon preceded eight nucleotides upstream by its own Shine–Dalgarno sequence. Each Shine–Dalgarno sequence can serve as an initiation site for translation, so all three polypeptides can be translated.

FIG. 4.19 Initiation in eukaryotes and in prokaryotes. (a) In eukaryotes, translation is initiated only at the 5' cap. (b) In prokaryotes, initiation takes place at any Shine–Dalgarno sequence; this mechanism allows a single mRNA to include coding sequences for multiple polypeptides.

A polycistronic mRNA results from transcription of a group of functionally related genes located in tandem along the DNA and transcribed as a single unit from one promoter. This type of gene organization is known as an [operon](#). Prokaryotes have many of their genes organized into operons because the production of a polycistronic mRNA allows all the protein products to be expressed together

whenever they are needed. Typically, the genes organized into operons are those whose products are needed either for successive steps in the synthesis of an essential small molecule, such as an amino acid, or for successive steps in the breakdown of a source of energy, such as a complex carbohydrate.

---

## CASE 1 LIFE'S ORIGINS: INFORMATION, HOMEOSTASIS, AND ENERGY

### How did the genetic code originate?

During transcription and translation, proteins and nucleic acids work together to convert the information stored in DNA into proteins. If we think about how such a system might have originated, however, we immediately confront a chicken-and-egg problem: cells need nucleic acids to make proteins, but proteins are required to make nucleic acids. Which came first? In [Chapter 3](#), we discussed the special features that make RNA an attractive candidate for both information storage and catalysis in early life. Early in evolutionary history, then, proteins had to be added to the mix. No one fully understands how they were incorporated, but researchers are looking closely at tRNA, the molecule involved in the “translating” step of translation.

In modern cells, tRNA shuttles amino acids to the ribosome, but an innovative hypothesis suggests that in early life tRNA-like molecules might have served a different function. This proposal holds that the early precursors of the ribosome were RNA molecules that facilitated the replication of other RNAs, not proteins. In this version of an RNA

world, precursors to tRNA would have shuttled nucleotides to growing RNA strands. Researchers hypothesize that tRNAs bound to amino acids may have acted as simple catalysts, facilitating more accurate RNA synthesis. Through time, amino acids brought into close proximity in the process of building RNA molecules might have polymerized to form polypeptide chains. From there, natural selection would favor the formation of polypeptides that enhanced replication of RNA molecules, bringing proteins into the chemistry of life.

#### Self-Assessment Questions

6. What are the relationships among the template strand of DNA, the codons in mRNA, anticodons in tRNA, and amino acids?
7. Which polypeptide sequences would you expect to result from a synthetic mRNA with the repeating sequence 5'-UUUGGGUUUGGGUUUGGG-3'?
8. What are the steps of translation? Name and describe each one.
9. Bacterial DNA containing an operon encoding three enzymes is introduced into chromosomal DNA in yeast (a eukaryote) in such a way that it is properly flanked by a promoter and a transcriptional terminator. The bacterial DNA is transcribed and the RNA correctly processed, but only the protein nearest the promoter is produced. Why?

## 4.3 PROTEIN ORIGINS AND EVOLUTION

The amino acid sequences of more than 1 million proteins are known, and the particular three-dimensional structure has been determined for each of more than 10,000 proteins. While few of the sequences and structures are identical, many are sufficiently similar that the proteins can be grouped into approximately 25,000 **protein families**. A protein family is a group of proteins that are structurally and functionally related as a result of their shared evolutionary history.

Why are there not more types of proteins? The number of possible sequences is unimaginably large. For example, for a polypeptide of only 62 amino acids, there are  $20^{62}$  possible sequences (because each of the 62 positions could be occupied by any of the 20 amino acids). The number  $20^{62}$  equals approximately  $10^{80}$ ; this number is also the estimated total number of electrons, protons, and neutrons in the entire universe! So why are there so few protein families? The most likely answer is that the chance that any random sequence of amino acids would fold into a stable configuration and carry out some useful function in the cell is very close to zero.

### Most proteins are composed of modular folding domains.

If functional proteins are so unlikely, how could life have evolved? The answer is that the earliest proteins were probably much shorter than modern proteins and needed only a trace of function. Only as proteins evolved through billions of years did they become progressively longer

and more specialized in their functions. Many protein families that exist today exhibit small regions of three-dimensional structure in which the protein folding is similar. These regions range in length from 25 to 100 or more amino acids. A region of a protein that folds in a similar way relatively independently of the rest of the protein is known as a **folding domain**.

Two examples of folding domains are illustrated in [Fig. 4.20](#). Many folding domains are functional units in themselves. The folding domain called a TIM barrel ([Fig. 4.20a](#)) is named after the enzyme triose phosphate isomerase, in which it is a prominent feature. The TIM barrel consists of alternating  $\alpha$  helices and parallel  $\beta$  sheets connected by loops. In many enzymes with a TIM barrel, the active site is formed by the loops at the carboxyl ends of the sheets. [Fig. 4.20b](#) is a  $\beta$  barrel formed from antiparallel  $\beta$  sheets.  $\beta$  barrel structures occur in proteins in some types of bacteria, usually in proteins that span the cell membrane, where the  $\beta$  barrel provides a channel that binds hydrophilic molecules.

Approximately 2500 folding domains are known, far fewer than the number of protein families. The reason for the discrepancy is that different protein families contain different combinations of folding domains. Modern protein families are composed of different combinations of a number of folding domains, each of which contributes some structural or functional feature of the protein. Different types of protein folds occur again and again in different contexts and combinations. The earliest proteins may have been little more than single folding domains that could aggregate to form more complex functional units. As life evolved, the proteins became longer by joining the DNA coding for the individual folding units together into a single molecule.

For example, human tissue plasminogen activator, a protein that is used in treating strokes and heart attacks because it dissolves blood clots, contains domains shared with cell-surface receptors, a domain shared with cellular growth factors, and a domain that folds into large loops facilitating protein–protein interactions. Hence, novel proteins do not always evolve from random combinations of amino acids; instead, they often evolve by joining already functional folding domains into novel combinations.

## Amino acid sequences evolve through mutation and selection.

Another important reason that complex proteins can evolve against seemingly long odds is that evolution proceeds stepwise through the processes of mutation and selection. A [mutation](#) is a change in the sequence of a gene. The process of mutation is discussed in [Chapter](#)

[14](#), but for now all you need to know is that mutations affecting proteins occur at random in regard to their effects on protein function. In protein-coding genes, some mutations may affect the amino acid sequence; others might change the level of protein expression or the time in development or type of cell in which the protein is produced. Here, we will consider only those mutations that change the amino acid sequence.

By way of analogy, we can use a simple word game. The object of the game is to change an ordinary English word into another meaningful English word by changing exactly one letter. Consider the word GONE. To illustrate “mutations” of the word that are random with respect to function (that is, random with respect to whether the change will yield a meaningful new word), we wrote a computer program that would choose one letter in GONE at random and replace it with a different random letter. The first 24 “mutants” of GONE are:

UONE GNNE GONJ GOZE

GONH GOLE GFNE XONE

NONE GKNE GJNE DONE

GCNE GONB GOIE GGNE

GONI GFNE GPNE GENE

BONE GOWE OONE GYNE

Most of the mutant words are gibberish, corresponding to the biological reality that most random amino acid replacements impair

protein function to some extent. Nevertheless, some mutant proteins function just as well as the original, and a precious few change function. In the word-game analogy, the mutants that can persist correspond to meaningful words, those words shown in red.

In a population of organisms, random mutations are retained or eliminated through the process of [selection](#) among individuals on the basis of their ability to survive and reproduce. This process was introduced in [Chapter 1](#) and is considered in greater detail in [Chapter 20](#), but the principle is straightforward. Most mutations that impair protein function will be eliminated because, if the function of the nonmutant protein contributes to survival and reproduction, the individuals carrying these mutations will leave fewer offspring than others. Mutations that do not impair function may remain in the population for long periods because their carriers survive and reproduce in normal numbers; a mutation of this type has no tendency to either increase or decrease in frequency over time. In contrast, individuals that carry the occasional mutation that improves protein function will survive and reproduce more successfully than others. Because of the enhanced reproduction, the mutant gene encoding the improved protein will gradually increase in frequency and spread throughout the entire population.

In the word game, any of the mutants in red may persist in the population. Suppose that one of them, GENE, is actually superior to GONE (considered more euphonious, perhaps). Then GENE will gradually displace GONE, and eventually GONE will be gone. Similar to the way in which one meaningful word may replace another, one

amino acid sequence may be replaced with a different one over the course of evolution.

A real-world example that mirrors the word game is found in the evolution of resistance in the malaria parasite to the drug pyrimethamine. This drug inhibits an enzyme known as dihydrofolate reductase, which the parasite needs to survive and reproduce inside red blood cells. Resistance to pyrimethamine is known to have evolved through a stepwise sequence of four amino acid replacements. In the first replacement, serine (S) at the 108th amino acid in the polypeptide sequence (position 108) was replaced with asparagine (N); then cysteine (C) at position 59 was replaced with arginine (R); asparagine (N) at position 51 was then replaced with isoleucine (I); and finally, isoleucine (I) at position 164 was replaced with leucine (L). If we list the amino acids according to their single-letter abbreviation in the order of their occurrence in the protein, the evolution of resistance followed this pathway:

$$\text{NCSI} \rightarrow \text{NC}\textcolor{red}{\text{NI}} \rightarrow \text{NR}\textcolor{red}{\text{NI}} \rightarrow \textcolor{red}{\text{IRNI}} \rightarrow \textcolor{red}{\text{IRNL}}$$

where the mutant amino acids are shown in red. Each successive amino acid replacement increased the level of resistance so that a greater concentration of drug was needed to treat the disease. The quadruple mutant **IRNL** is resistant to such high levels of pyrimethamine that the drug is no longer useful.

Depicted according to stepwise amino acid replacements, the analogy between the evolution of pyrimethamine resistance and the word game is clear. It should also be clear from our earlier discussion

that hundreds of other mutations causing amino acid replacements in the enzyme must have occurred in the parasite during the course of evolution, but only these amino acid changes occurring in this order persisted and increased in frequency because they conferred greater survival and reproduction of the parasite under treatment with the drug.

All of the steps in gene expression, including transcription and translation, are summarized in [Fig. 4.21](#).

FIG. 4.21 VISUAL SYNTHESIS: Gene Expression Integrating concepts from [Chapters 3](#) and [4](#)

### Self-Assessment Questions

10. What are two ways that proteins can acquire new functions in the course of evolution? Explain each one.
11. In the evolution of resistance in the malaria parasite to

pyrimethamine, what do you think happened to the mutations that decreased survival or reproduction of the parasites?

## CORE CONCEPTS SUMMARY

**4.1 MOLECULAR STRUCTURE OF PROTEINS:** Proteins are linear polymers of amino acids that form three-dimensional structures with specific functions.

An amino acid consists of an  $\alpha$  carbon connected by covalent bonds to an amino group, a carboxyl group, a hydrogen atom, and a side chain or R group. [page 71](#)

The 20 common amino acids differ in their R groups. Amino acids are categorized by the chemical properties of their R groups—hydrophobic, basic, acidic, polar—and by special structures. [page 72](#)

Amino acids are connected by peptide bonds to form proteins. [page 73](#)

The primary structure of a protein is its amino acid sequence. This structure determines how a protein folds, which in turn determines how it functions. [page 74](#)

The secondary structure of a protein results from the interactions of nearby amino acids. Examples include the  $\alpha$  helix and  $\beta$  sheet. [page 74](#)

The tertiary structure of a protein is its three-dimensional shape, which results from long-range interactions of amino acid R groups. [page 76](#)

Some proteins are made up of several polypeptide subunits; this group of subunits is the protein's quaternary structure. [page 77](#)

Chaperones help some proteins fold properly. [page 77](#)

**4.2 PROTEIN SYNTHESIS:** Translation is the process by which the sequence of bases in messenger RNA specifies the order of successive amino acids in a newly synthesized protein.

Translation requires many cellular components, including ribosomes, tRNAs, and proteins. [page 80](#)

Ribosomes are composed of a small and a large subunit, each consisting of RNA and protein; the large subunit contains three tRNA-binding sites that play different roles in translation. [page 80](#)

An mRNA transcript of a gene has three possible reading frames composed of three-nucleotide codons. [page 80](#)

tRNAs have an anticodon that base pairs with the codon in the mRNA and carries a specific amino acid. [page 80](#)

Aminoacyl tRNA synthetases attach specific amino acids to tRNAs. [page 81](#)

The genetic code defines the relationship between the three-letter codons of nucleic acids and their corresponding amino acids. It was deciphered using synthetic RNA molecules. [page 82](#)

The genetic code is redundant, in that many amino acids are specified by more than one codon. [page 82](#)

Translation consists of three steps: initiation, elongation, and termination. [page 84](#)

**4.3 PROTEIN ORIGINS AND EVOLUTION:** Proteins evolve

through mutation and selection and by combining functional units.

A protein family is a group of proteins that are structurally and functionally related. [page 86](#)

There are far fewer protein families than the total number of possible proteins because the probability that a random sequence of amino acids will fold properly to carry out a specific function is very small. [page 86](#)

A region of a protein that folds in a particular way and that carries out a specific function is called a folding domain. [page 86](#)

Proteins evolve by combining different folding domains. [page 87](#)

Proteins also evolve through changes in their amino acid sequence, which occurs by mutation and selection. [page 87](#)

## CHAPTER 5 Organizing Principles

### Lipids, Membranes, and Cell Compartments

Dr. Jeremy Burgess/Science Source.

## CORE CONCEPTS

**5.1 STRUCTURE OF CELL MEMBRANES:** Cell membranes are composed of lipids, proteins, and carbohydrates.

**5.2 MOVEMENT IN AND OUT OF CELLS:** The plasma membrane is a selective barrier that controls the movement of molecules between the inside and the outside of the cell.

**5.3 INTERNAL ORGANIZATION OF CELLS:** Cells can be classified as prokaryotes or eukaryotes, which differ in their degree of internal compartmentalization.

**5.4 THE ENDOMEMBRANE SYSTEM:** The endomembrane system is an interconnected system of membranes that defines spaces in the cell, synthesizes important molecules, and traffics and sorts these molecules in and out of the cell.

**5.5 MITOCHONDRIA AND CHLOROPLASTS:** Mitochondria and chloroplasts are organelles that harness energy, and likely evolved from free-living prokaryotes.

---

“With the discovery of the cell, biologists found their atom.” So stated François Jacob, the French biologist who shared the Nobel Prize in Physiology or Medicine in 1965. Just as the atom is the smallest, most basic unit of matter, the cell is the smallest, most basic unit of living organisms. All organisms, from single-celled algae to complex multicellular organisms like humans, are made up of cells. Therefore, essential properties of life, including growth, reproduction, and metabolism, must be understood in terms of cell structure and function.

Cells were first seen sometime around 1665, when the English scientist Robert Hooke built a microscope that he used to observe thin sections of dried cork tissue derived from plants. In these sections, Hooke observed arrays of small cavities and named them “cells” ([Fig.](#)

[5.1](#)). Although Hooke was probably looking at the cell walls of empty (rather than living) cells, his observations nevertheless led to the concept that cells are the fundamental unit of life. Later in the seventeenth century, the Dutch microbiologist Anton van Leeuwenhoek greatly improved the magnifying power of microscope lenses, enabling him to see and describe unicellular organisms, including bacteria, protists, and algae. Today, modern microscopy provides unprecedented detail and a deeper understanding of the inner architecture of cells.

Cells differ in size and shape, but they share many features. This similarity in the microscopic organization of all living organisms led to the development in the middle of the nineteenth century of one of the pillars of modern biology: **cell theory**. Based on the work and ideas of Matthias Schlieden, Theodor Schwann, Rudolf Virchow, and others, cell theory states that all organisms are made up of cells, that the cell is the fundamental unit of life, and that cells come from preexisting cells. There is no life without cells, and the cell is the smallest unit of life.

This chapter focuses on cells and their internal organization. We pay particular attention to the key role that membranes play in separating a cell from the external environment and in defining structural and functional spaces within cells.

# 5.1 STRUCTURE OF CELL MEMBRANES

Cells are defined by membranes. Membranes physically separate cells from their external environment and define spaces within many cells that allow them to carry out their diverse functions.

Lipids are the main component of cell membranes. They have properties that allow them to form a barrier in an aqueous (watery) environment. Membranes are not, however, made up of only lipids. Proteins are often embedded in or associated with the membrane, where they perform important functions such as transporting molecules. Carbohydrates can also be found in cell membranes, usually attached to lipids (glycolipids) and proteins (glycoproteins).

## Cell membranes are composed of two layers of lipids.

The major types of lipids found in cell membranes are phospholipids, which were introduced in [Chapter 2](#). Most phospholipids are made up of a glycerol backbone attached to a phosphate group and two fatty acids ([Fig. 5.2](#)). The phosphate head group is hydrophilic (“water-loving”) because it is polar, enabling it to form hydrogen bonds with water. By contrast, the two fatty acid tails are hydrophobic (“water-fearing”) because they are nonpolar and do not form hydrogen bonds with water. Molecules with both hydrophilic and hydrophobic regions in a single molecule are termed [amphipathic](#).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

**FIG. 5.2 Phospholipid structure.** Phospholipids, the major component of cell membranes, are made up of glycerol attached to a phosphate-containing head group and two fatty acid tails. They are amphipathic because they have both hydrophilic and hydrophobic domains.

In an aqueous environment, amphipathic molecules such as phospholipids behave in an interesting way. Namely, they spontaneously arrange themselves into various structures in which the polar head groups on the outside interact with water and the nonpolar tail groups come together on the inside away from water. This arrangement results from the tendency of polar molecules like water to exclude nonpolar molecules or nonpolar groups of molecules.

The shape of the structure is determined by the bulkiness of the head group relative to the hydrophobic tails. For example, lipids with bulky heads and a single hydrophobic fatty acid tail are wedge-shaped and pack into spherical structures called **micelles** (**Fig. 5.3a**). By contrast, lipids with less bulky head groups and two hydrophobic tails are roughly rectangular and form a **bilayer** (**Fig. 5.3b**). A lipid bilayer is a structure formed of two layers of lipids in which the hydrophilic heads are the outside surfaces of the bilayer and the hydrophobic tails are sandwiched in between, isolated from contact with the aqueous environment.

The bilayers form closed structures with an inner space because free edges would expose the hydrophobic chains to the aqueous environment. This organization in part explains why bilayers are effective cell membranes. It also explains why membranes are self-healing. Small tears in a membrane are rapidly sealed by the spontaneous rearrangement of the lipids surrounding the damaged region because of the tendency of water to exclude nonpolar molecules.

## CASE 1 LIFE'S ORIGINS: INFORMATION, HOMEOSTASIS, AND ENERGY

### How did the first cell membranes form?

What are the consequences of the ability of phospholipids to form a bilayer when placed in water? The bilayer structure forms spontaneously, dependent solely on the properties of the phospholipid and without the action of an enzyme, as long as the concentration of free phospholipids is high enough and the pH of the solution is similar to that of a cell. The pH is important because it ensures that the head groups are in their ionized (charged) form and suitably hydrophilic. Thus, if phospholipids are added to a test tube of water at neutral pH, they spontaneously form spherical bilayer structures called liposomes that surround a central space ([Fig. 5.3c](#)). As the liposomes form, they may capture macromolecules present in solution.

Such a process may have been at work in the early evolution of life on Earth. Experiments show that liposomes can form, break, and reform in environments such as tidal flats that are repeatedly dried and flooded with water. The liposomes can even grow, incorporating more and more lipids from the environment, and capture nucleic acids and other molecules in their interiors. Depending on their chemical composition, early membranes might have been either leaky or almost impervious to the molecules of life. Over time, they evolved in such a way as to allow at least limited molecular traffic between the

environment and the cell interior. At some point, new lipids no longer had to be incorporated from the environment. Instead, proteins guided lipid synthesis within the cell, although how this switch to protein-mediated synthesis happened remains uncertain.

All evidence suggests that membranes formed originally by straightforward physical processes, but that their composition and function evolved over time. François Jacob once said that evolution works more like a tinkerer than an engineer, modifying already existing materials rather than designing systems from scratch. It seems that the evolution of membranes is no exception to this pattern.

## Cell membranes are dynamic.

Lipids freely associate with one another because of the extensive van der Waals forces between their fatty acid tails ([Chapter 2](#)). These weak interactions are easily broken and re-formed, so lipid molecules are able to move within the plane of the membrane, sometimes very rapidly: a single phospholipid can move across the entire length of a bacterial cell in less than 1 second. Lipids can also rapidly rotate around their vertical axis, and individual fatty acid chains are able to flex, or bend. As a result, membranes are dynamic: they are continually moving, forming, and re-forming during the lifetime of a cell.

Because membrane lipids are able to move in the plane of the membrane, the membrane is said to be **fluid**. The degree of membrane fluidity depends on which types of lipid make up the membrane. In a single layer of the lipid bilayer, the strength of the van der Waals interactions between the lipids' tails depends on the length of the fatty

acid tails and the presence of double bonds between neighboring carbon atoms. The longer the fatty acid tails, the more surface is available to participate in van der Waals interactions. The tighter packing that results tends to reduce lipid mobility. Saturated fatty acid tails, which have no double bonds, are straight and tightly packed—again reducing mobility ([Fig. 5.4a](#)). The double bonds in unsaturated fatty acids introduce kinks in the fatty acid tails, reducing the tightness of packing and enhancing lipid mobility in the membrane ([Fig. 5.4b](#)).

In addition to phospholipids, cell membranes often contain other types of lipids, which can also influence membrane fluidity. For example, [cholesterol](#) is a major component of animal cell membranes, representing approximately 30% by mass of the membrane lipids. Like phospholipids, cholesterol is amphipathic, with both hydrophilic and hydrophobic groups being present in the same molecule. In cholesterol, the hydrophilic region is simply a hydroxyl group ( $-\text{OH}$ ) and the

hydrophobic region consists of four interconnected carbon rings with an attached hydrocarbon chain ([Fig. 5.5](#)). This structure allows a cholesterol molecule to insert itself into the lipid bilayer so that its head group interacts with the hydrophilic head group of phospholipids, while the ring structure participates in van der Waals interactions with the fatty acid chains.

Cholesterol increases or decreases membrane fluidity depending on the temperature. At the temperatures typically found in a cell, cholesterol decreases membrane fluidity because the interaction of the rigid ring structure of cholesterol with the phospholipid fatty acid tails reduces the mobility of the phospholipids. However, at low temperatures, cholesterol increases membrane fluidity because it prevents phospholipids from packing tightly with other phospholipids. Thus, cholesterol helps maintain a consistent state of membrane fluidity by preventing dramatic transitions from a fluid to a solid state.

For many decades, it was thought that the various types of lipids

found in the membrane were randomly distributed throughout the bilayer. More recent studies show that specific types of lipids, such as sphingolipids, sometimes assemble into defined patches called **lipid rafts**. Cholesterol and other membrane components such as proteins also appear to accumulate in some of these regions. Thus, membranes are not always a uniform fluid bilayer, but instead can contain regions with discrete components.

Although lipids are free to move in the plane of the membrane, the spontaneous transfer of a lipid between layers of the bilayer, known as lipid flip-flop, is very rare. This is not surprising because flip-flop requires the hydrophilic head group to pass through the hydrophobic interior of the membrane. As a result, little exchange of components occurs between the two layers of the membrane, which in turn allows the two layers to differ in composition. In fact, in many membranes, different types of lipids are present primarily in one layer or the other.

## Proteins associate with cell membranes in different ways.

Most membranes contain proteins as well as lipids. For example, proteins represent as much as 50% by mass of the membrane of a red blood cell. Membrane proteins serve different functions (**Fig. 5.6**). Some act as **transporters**, moving ions or other molecules across the membrane. Other membrane proteins act as **receptors**, which allow the cell to receive signals from the environment. Still others are **enzymes** that catalyze chemical reactions or **anchors** that attach to other proteins and help to maintain cell structure and shape.

FIG. 5.6 Functions of membrane proteins.

The various membrane proteins can be classified into two groups depending on how they associate with the membrane ([Fig. 5.7](#)).

**Integral membrane proteins** are permanently associated with cell membranes and cannot be separated from the membrane experimentally without destroying the membrane itself. **Peripheral membrane proteins** are temporarily associated with the lipid bilayer or with integral membrane proteins through weak noncovalent interactions. They are easily separated from the membrane by simple experimental procedures that leave the structure of the membrane intact.

FIG. 5.7 Integral and peripheral membrane proteins. Integral membrane proteins

are permanently associated with the membrane. Peripheral membrane proteins are temporarily associated with one or other of the two lipid bilayers or with an integral membrane protein.

Most integral membrane proteins are **transmembrane proteins** that span the entire lipid bilayer, as shown in [Fig. 5.7](#). These proteins are composed of three regions: two hydrophilic regions, one protruding from each face of the membrane, and a connecting hydrophobic region that spans the membrane. This structure allows for separate functions and capabilities of each end of the protein. For example, the hydrophilic region on the external side of a receptor can interact with signaling molecules, whereas the hydrophilic region of that receptor protein on the internal side of the membrane often interacts with other proteins in the cytoplasm of the cell to pass along the message.

Peripheral membrane proteins may be associated with either the internal or external side of the membrane ([Fig. 5.7](#)). These proteins interact either with the polar heads of lipids or with integral membrane proteins by weak noncovalent interactions such as hydrogen bonds. Peripheral membrane proteins are only transiently associated with the membrane and can play a role in transmitting information received from external signals. Other peripheral membrane proteins limit the ability of transmembrane proteins to move within the membrane and assist proteins in clustering in lipid rafts.

Proteins, like lipids, are free to move in the membrane. How do we know this? The mobility of proteins in the cell membrane can be demonstrated using an elegant experimental technique called fluorescence recovery after photobleaching (FRAP), described in [Fig.](#)

## 5.8.

HOW DO WE KNOW?

### FIG. 5.8

## Do proteins move in the plane of the membrane?

### BACKGROUND

Fluorescent recovery after photobleaching (FRAP) is a technique used to measure mobility of molecules in the plane of the membrane. A fluorescent dye is attached to proteins embedded in the cell membrane in a process called labeling. Labeling all the proteins in a membrane creates a fluorescent cell that can be visualized with a fluorescence microscope. A laser is then used to bleach a small area of the membrane, leaving a nonfluorescent spot on the surface of the cell.

### HYPOTHESIS

If membrane components such as proteins move in the plane of the membrane, the bleached spot should become fluorescent over time as unbleached fluorescent molecules move into the bleached area. If membrane components do not move, the bleached spot should remain intact.

### EXPERIMENT AND RESULTS

Over time, fluorescence appears in the bleached area, telling us that fluorescent proteins that were not bleached moved into the bleached area.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

PHOTO SOURCE: FRAP of cytoplasmic EGFP in living HeLa cells, performed using an UltraVIEW® spinning disk confocal system (PerkinElmer Inc.). HeLa cells were transfected with pEGFP-C1 (Clontech Laboratories, Inc.) using GeneJuice® transfection reagent (Novagen®). A region of interest in the cytoplasm was photobleached using the UltraVIEW® photokinesis unit, and the recovery of fluorescence in this region was observed. (Fluorescence Recovery After Photobleaching (FRAP) using the UltraVIEW PhotoKinesis accessory, PerkinElmer Technical Note).

## CONCLUSION

The gradual recovery of fluorescence in the bleached area indicates that proteins move in the plane of the membrane.

SOURCE Peters, R., et al. 1974. "A Microfluorimetric Study of Translational Diffusion in Erythrocyte Membranes." *Biochimica et Biophysica Acta* 367:282–294.

The idea that lipids and proteins coexist in the membrane, and that both are able to move in the plane of the membrane, led American biologists S. Jonathan Singer and Garth Nicolson to propose the **fluid mosaic model** in 1972. According to this model, the lipid bilayer is a

fluid structure within which molecules move laterally, and is a mosaic (a mixture) of two types of molecules, lipids and proteins.

#### Self-Assessment Questions

1. How do lipids with hydrophilic and hydrophobic regions behave in an aqueous environment?
2. Like cell membranes, many fats and oils are made up in part of fatty acids. Most animal fats (like butter) are solid at room temperature, whereas plant fats (like canola oil) tend to be liquid. Can you predict which type of fat contains saturated fatty acids, and which type contains unsaturated fatty acids?
3. What are two ways in which proteins associate with membranes?
4. What would happen in the FRAP experiment if proteins did not move in the plane of a membrane?

## 5.2 MOVEMENT IN AND OUT OF CELLS

Phospholipids with embedded proteins make up the membrane surrounding all cells. This membrane, called the **plasma membrane**, is a fundamental, defining feature of all cells. It is the boundary that defines the space of the cell, separating its internal contents from the surrounding environment. But the plasma membrane is not simply a passive boundary or wall. Instead, it serves an active and important function. The environment outside the cell is constantly changing. In contrast, the internal environment of a cell operates within a narrow window of conditions, such as a particular pH range or salt concentration. It is the plasma membrane that actively maintains intracellular conditions compatible with life.

The cells of many organisms also have a **cell wall** external to the plasma membrane. The cell wall plays an important role in maintaining the shape of these cells. In this section, we consider the functions performed by these two key structures.

### The plasma membrane maintains homeostasis.

The active maintenance of a constant environment within the cells, known as **homeostasis**, is a critical attribute of cells and of life itself. Chemical reactions and protein folding, for example, are carried out efficiently only within a narrow range of conditions. How does the plasma membrane maintain homeostasis? The answer is that it is **selectively permeable** (or semipermeable). This means that the plasma

membrane lets some molecules in and out freely; it lets others in and out only under certain conditions; and it prevents still other molecules from passing through at all.

The membrane's ability to act as a selective barrier is the result of the combination of lipids and embedded proteins of which it is composed. The hydrophobic interior of the lipid bilayer prevents ions and charged polar molecules from moving across it. Furthermore, many macromolecules such as proteins and polysaccharides are too large to cross the plasma membrane on their own. By contrast, gases such as oxygen and carbon dioxide, and nonpolar molecules such as lipids, can move across the lipid bilayer. Small uncharged polar molecules, such as water, are able to move through the lipid bilayer to a very limited extent, but this movement is not biologically significant. However, protein channels and transporters in the membrane can greatly facilitate the movement of molecules, including ions, water, and nutrients, that cannot cross the lipid bilayer on their own.

The identity and abundance of these membrane-associated proteins vary among cell types, reflecting the specific functions of different cells. For example, cells in your gut contain membrane transporters that specialize in the uptake of glucose, whereas nerve cells have different types of ion channels that are involved in electrical signaling.

## Passive transport involves diffusion.

The simplest form of movement into and out of cells is passive transport. Passive transport works by [diffusion](#), which is the random movement of molecules. Molecules are always moving in their

environments. For example, molecules in water at room temperature move around at about 500 m/sec, which means that they can move only about 3 molecular diameters before they run into another molecule, leading to about 5 trillion collisions per second. The frequency with which molecules collide has important consequences for chemical reactions, which depend on the interaction of molecules ([Chapter 6](#)).

Diffusion leads to a net movement of the substance from one region to another when there is a concentration gradient in the distribution of a molecule, meaning that there are areas of higher and lower concentrations. In this case, diffusion results in net movement of the molecule from an area of higher concentration to an area of lower concentration. When there is no longer a concentration gradient, net movement stops but movement of molecules in both directions continues ([Fig. 5.9](#)).

FIG. 5.9 Diffusion, the movement of molecules due to random motion. Net movement of molecules occurs when there are concentration differences.

Some molecules diffuse freely across the plasma membrane as a result of differences in concentrations between the inside and the outside of a cell. Oxygen and carbon dioxide, for example, move into and out of the cell in this way. Certain hydrophobic molecules, such as triacylglycerols ([Chapter 2](#)), are also able to diffuse through the cell membrane, which is not surprising since the lipid bilayer is also hydrophobic.

Some molecules that cannot move across the lipid bilayer directly can move passively toward a region of lower concentration through protein transporters. When a molecule moves by diffusion through a membrane protein and bypasses the lipid bilayer, the process is called **[facilitated diffusion](#)**. Diffusion and facilitated diffusion both result from the random motion of molecules, and net movement of the substance occurs when there are concentration differences ([Fig. 5.10](#)). In the case of facilitated diffusion, the molecule moves through a membrane transporter, whereas in the case of simple diffusion, the molecule moves directly through the lipid bilayer.

Two types of membrane transporters may be used. The first type is a **channel**, which provides an opening between the inside and outside of the cell through which certain molecules can pass, depending on their shape and charge. Some membrane channels are gated, which means that they open in response to some sort of signal, which may be chemical or electrical ([Chapter 9](#)). The second type of membrane transporter is a **carrier**, which binds to and then transports specific molecules. Membrane carriers exist in two conformations: one that is open to one side of the cell, and another that is open to the other side of the cell. Binding of the transported molecule induces a conformational change in the membrane protein, allowing the molecule to be transported across the lipid bilayer, as shown on the right in [Fig. 5.10](#).

Up to this point, we have focused our attention on the movement of molecules (the solutes) in water (the solvent). We now take a different

perspective and focus instead on water movement. Water moves into and out of cells by passive transport. Although the central part of the phospholipid bilayer is hydrophobic, water molecules are small enough to move passively through the bilayer to a very limited extent by simple diffusion. However, this movement does not appear to be biologically important. Instead, water moves through the plasma membrane by protein channels called [aquaporins](#). These channels allow water to move much more readily across the plasma membrane by facilitated diffusion than is possible by simple diffusion.

The net movement of a solvent such as water across a selectively permeable membrane such as the plasma membrane is known as [osmosis](#). As in any form of diffusion, water moves from regions of higher *water* concentration to regions of lower *water* concentration ([Fig. 5.11](#)). Because water is a solvent within which nutrients such as glucose or ions such as sodium or potassium are dissolved, water concentration decreases as solute concentration increases. Therefore, it is sometimes easier to think about water moving from regions of lower *solute* concentration toward regions of higher *solute* concentration. Either way, the direction of water movement is the same.

a selectively permeable membrane from an area of lower solute concentration to an area of higher solute concentration.

During osmosis, the net movement of water toward the side of the membrane with higher solute concentration continues until a concentration gradient no longer exists or until the movement is opposed by another force. This force could be pressure due to gravity (in the case of [Fig. 5.11](#)) or the cell wall (in the case of plants, fungi, and bacteria, as described later in this chapter). Osmosis can therefore be prevented by applying a force to the compartment with the higher solute concentration. The pressure that would need to be applied to stop water from moving into a solution by osmosis is referred to as the [osmotic pressure](#). Osmotic pressure is a way of describing the tendency of a solution to “draw water in” by osmosis ([Chapter 39](#)).

## Primary active transport uses the energy of ATP.

Passive transport works to the cell’s advantage only if the concentration gradient is in the right direction, from higher on the outside to lower on the inside for nutrients that the cell needs to take in, and from higher on the inside and lower on the outside for wastes that the cell needs to export. However, many of the molecules that cells require are not highly concentrated in the environment. Although some of these molecules can be synthesized by the cell, others must be taken up from the environment. In other words, cells have to move these substances from areas of lower concentration to areas of higher concentration. The “uphill” movement of substances against a

concentration gradient, called **active transport**, requires energy. The transport of many kinds of molecules across membranes requires energy, either directly or indirectly. In fact, most of the energy used by a cell goes into keeping the inside of the cell different from the outside, a function carried out by proteins in the plasma membrane.

During active transport, cells move substances through transport proteins embedded in the cell membrane. Some of these proteins act as pumps, using energy directly to move a substance into or out of a cell. A good example is the sodium–potassium pump (**Fig. 5.12**). Within cells, sodium is kept at concentrations much lower than in the exterior environment; the opposite is true of potassium. Therefore, both sodium and potassium have to be moved against a concentration gradient. The sodium–potassium pump actively moves sodium out of the cell and potassium into the cell. This movement of ions takes energy, which comes from the chemical energy stored in adenosine triphosphate (ATP). Active transport that uses energy directly in this manner is called **primary active transport**. Note that the sodium ions and potassium ions move in opposite directions; protein transporters that work in this way are referred to as antiporters. Other transporters move two molecules in the same direction, and are referred to as symporters or cotransporters.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 5.12 Primary active transport. The sodium–potassium pump is a membrane protein that uses the energy stored in ATP to move sodium and potassium ions against their concentration gradients.

## Secondary active transport is driven by an electrochemical gradient.

Active transport can work in yet another way. Because small ions cannot cross the lipid bilayer, many cells use a transport protein to build up the concentration of a small ion on one side of the membrane. The resulting concentration gradient stores potential energy that can be harnessed to drive the movement of other substances across the membrane against their concentration gradient.

For example, some cells actively pump protons ( $\text{H}^+$ ) across the cell membrane using ATP ([Fig. 5.13a](#)). As a result, in these cells the concentration of protons is higher on one side of the membrane and lower on the other side. In other words, the pump generates a concentration gradient, also called a chemical gradient because the entity forming the gradient is a chemical ([Fig. 5.13b](#)). We have already seen that concentration differences favor the movement of protons

back to the other side of the membrane. By blocking the movement of protons to the other side, the lipid bilayer creates a store of potential energy, just as a dam or battery does.

FIG. 5.13 Secondary active transport. Protons are pumped across a membrane by (a) primary active transport, resulting in (b) an electrochemical gradient, which drives (c) the movement of another molecule against its concentration gradient.

In addition to the chemical gradient, another force favors the movement of protons back across the membrane: a difference in charge. Because protons carry a positive charge, the side of the membrane with more protons is more positive than the other side. This difference in charge is called an electrical gradient. Protons (and other ions) move from areas of like charge to areas of unlike charge, driven by an electrical gradient. A gradient that has both charge and chemical components is known as an **electrochemical gradient** (Fig. 5.13b).

If protons are then allowed to pass through the cell membrane by a

transport protein, they will move down their electrochemical gradient toward the region of lower proton concentration. These transport proteins can use the movement of protons to drive the movement of other molecules against their concentration gradient ([Fig. 5.13c](#)). The movement of protons is always from regions of higher to lower concentration, whereas the movement of the coupled molecule is from regions of lower to higher concentration. Because the movement of the coupled molecule is driven by the movement of protons and not by ATP directly, this form of transport is called **[secondary active transport](#)**. Secondary active transport uses the potential energy of an electrochemical gradient to drive the movement of molecules; by contrast, primary active transport uses the chemical energy of ATP directly.

The use of an electrochemical gradient as a temporary energy source is a common cellular strategy. For example, cells use a sodium electrochemical gradient generated by the sodium–potassium pump to transport glucose and amino acids into cells. In addition, cells use a proton electrochemical gradient to move other molecules and, as we discuss later in this chapter and in [Chapter 7](#), to synthesize ATP.

## Many cells maintain size and composition using active transport.

Many cells use active transport to maintain their size. Consider human red blood cells placed in a variety of solutions ([Fig. 5.14](#)). If a red blood cell is placed in a hypertonic solution (one with a higher solute concentration than that inside the cell), water leaves the cell by osmosis and the cell shrinks. By contrast, if a red blood cell is placed in a

hypotonic solution (one with a lower solute concentration than that inside the cell), water moves into the cell by osmosis and the cell lyses, or bursts. Animal cells solve the problem of water movement in part by keeping the intracellular fluid isotonic (that is, at the same solute concentration) with the extracellular fluid. Cells use the active transport of ions to maintain equal concentrations inside and out, and the sodium–potassium pump plays an important role in keeping the inside of the cell isotonic with the extracellular fluid.

FIG. 5.14 Changes in red blood cell shape due to osmosis. Red blood cells shrink, swell, or burst because of net water movement driven by differences in solute concentration between the inside and the outside of the cell.

Human red blood cells avoid shrinking or bursting by maintaining an intracellular environment isotonic with the extracellular environment, meaning the blood. But what about a single-celled organism, like *Paramecium*, swimming in a freshwater lake? In this case, the extracellular environment is hypotonic compared with the concentration in the cell's interior. As a result, *Paramecium* faces the risk of bursting from water moving in by osmosis. *Paramecium* and

some other single-celled organisms contain [contractile vacuoles](#) that solve this problem. Contractile vacuoles are compartments that take up excess water from inside the cell and then, by contraction, expel it into the external environment. The mechanism by which water moves into the contractile vacuoles differs depending on the organism. The contractile vacuoles of some organisms take in water through aquaporins, while the contractile vacuoles of other organisms first take in protons through proton pumps, with water following by osmosis.

## The cell wall provides another means of maintaining cell shape.

As we have seen, animals often maintain cell size by using active transport to keep the inside and outside of the cell isotonic. How do organisms such as plants, fungi, and bacteria maintain cell size and shape? A key feature of these organisms is the cell wall surrounding the plasma membrane ([Fig. 5.15](#)). The cell wall plays a critical role in the maintenance of cell size and shape. When Hooke looked at cork through his microscope, what he saw was not living cells but rather the remains of cell walls.

Source: Biophoto Associates/Getty Images.

FIG. 5.15 The plant cell wall and vacuoles. The plant cell wall is a rigid structure that maintains the shape of the cell. The pressure exerted by water absorbed by vacuoles also provides support.

The cell wall provides structural support and protection for the cell. Because the cell wall is rigid and resists expansion, it allows pressure to build up when water enters a cell. The force exerted by water pressing against an object is called **turgor pressure**. Turgor pressure builds as a result of water moving by osmosis into cells surrounded by a cell wall. Cells contain high concentrations of solutes. Recall that when an animal cell, such as a red blood cell, is placed in a hypotonic solution, it swells until it bursts. By contrast, when a plant cell is placed in a hypotonic solution, water enters the cell by osmosis until the turgor pressure created by the cell wall increases to a level to stop osmosis. Turgor pressure develops because the cell wall resists being stretched and pushes back on the interior of the cell, just as a balloon pushes back on the air inside.

The pressure exerted by water inside the cell on the cell wall

provides structural support for many organisms that is similar in function to the support provided by animals' skeletons. In addition, plant and fungal cells have another structure, called the **vacuole** (different from the contractile vacuole), that absorbs water and contributes to turgor pressure ([Fig. 5.15](#)). Its functioning explains why plants wilt when dehydrated: the loss of water from the vacuoles reduces turgor pressure, so the cells can no longer maintain their shape within the cell wall. Plant vacuoles have many other functions and are often the most conspicuous feature of plant cells. They also explain in part why plant cells are typically larger than animal cells and can store water, as well as nutrients, ions, and wastes.

The cell wall is made up of many different components, including carbohydrates and proteins. The specific components differ depending on the organism. The plant cell wall is composed of polysaccharides, including cellulose, a polymer of the sugar glucose. Cellulose is the most abundant biological material in nature. Many types of algae have cell walls made up of cellulose, as in plants, but others have cell walls made of silicon or calcium carbonate. Fungi have cell walls made of chitin, another polymer of sugars. In bacteria, the cell wall is made up primarily of peptidoglycan, a polymer of amino acids and sugars.

#### Self-Assessment Questions

5. What are the roles of lipids and proteins in maintaining the selective permeability of membranes?
6. A container is divided into two compartments by a membrane that is fully permeable to water and small ions. Water is added to

one side of the membrane (side A), and a 5% solution of sodium chloride (NaCl) is added to the other (side B). In which direction will water molecules move? In which direction will sodium and chloride ions move? When the concentration is equal on both sides, will diffusion stop?

7. What is the difference between passive and active transport?
8. In the absence of the sodium–potassium pump, the extracellular solution becomes hypotonic relative to the inside of the cell. Poisons such as the snake venom ouabain can interfere with the action of the sodium–potassium pump. What are the consequences for the cell?
9. What are three different ways in which cells maintain size and shape?

## 5.3 INTERNAL ORGANIZATION OF CELLS

In addition to the plasma membrane, many cells contain membrane-bound regions within which specific functions are carried out. Such a cell can be compared to a large factory with many different rooms and departments. Each department has a specific function and internal organization that contribute to the work of the factory. In this section, we give an overview of two broad classes of cells that can be distinguished by the presence or absence of these membrane-enclosed compartments.

### Eukaryotes and prokaryotes differ in internal organization.

All cells have a plasma membrane and contain genetic material. In some cells, this genetic material is housed in a membrane-bound space called the **nucleus**. Cells can be divided into two classes based on the absence or presence of a nucleus ([Chapter 1](#)). **Prokaryotes**, including bacteria and archaeons, lack a nucleus; **eukaryotes**, including animals, plants, fungi, and protists, have a nucleus ([Fig. 5.16](#)). The presence of a nucleus in eukaryotes allows for the processes of transcription and translation to be separated in time and space. This separation, in turn, allows for more complex ways to regulate gene expression than are possible in prokaryotes ([Chapter 18](#)).

FIG. 5.16 Prokaryotic and eukaryotic cells. Prokaryotic cells lack a nucleus and extensive internal compartmentalization. Eukaryotic cells have a nucleus and extensive internal compartmentalization.

There are other differences between prokaryotes and eukaryotes. For example, we saw in [Chapter 3](#) that transcription and translation differ in some ways in prokaryotes and eukaryotes. In addition, there are differences in the types of lipids that make up their cell membranes. In mammals, cholesterol is present in cell membranes. Cholesterol belongs to a group of chemical compounds known as sterols, which are molecules containing a hydroxyl group attached to a four-ringed structure. In eukaryotes other than mammals, diverse sterols are synthesized and present in cell membranes. Most prokaryotes do not synthesize sterols, but some synthesize compounds called hopanoids.

These five-ringed structures are thought to serve a function similar to that of cholesterol in mammalian cell membranes.

In spite of these and other differences between prokaryotes and eukaryotes, it is the absence or presence of a nucleus that defines the two groups. However, from an evolutionary perspective, archaeons and eukaryotes are more closely related to each other than either are to bacteria. For example, archaeons share with eukaryotes many genes involved in transcription and translation, and DNA is packaged with histones in both groups.

## Prokaryotic cells lack a nucleus and extensive internal compartmentalization.

Prokaryotes do not have a nucleus—that is, there is no physical barrier separating the genetic material from the rest of the cell. Instead, the DNA is concentrated in a discrete region of the cell interior known as the **nucleoid**. Bacteria often contain additional small circular molecules of DNA known as **plasmids** that carry a few genes. Plasmids are commonly transferred between bacteria through the action of threadlike structures known as **pili** (singular, **pilus**), which extend from one cell to another. Genes for antibiotic resistance are commonly transferred in this way, which accounts for the quick spread of antibiotic resistance among bacterial populations.

Although the absence of a nucleus is a defining feature of prokaryotes, other features also stand out. For example, prokaryotes are

small, typically just 1–2 micrometers (a micrometer is 1/1,000,000 of a meter) in diameter or smaller. By contrast, eukaryotic cells are commonly much larger, on the order of 10 times larger in diameter and 1000 times larger in volume. The small size of prokaryotic cells means that they have a relatively high ratio of surface area to volume, which makes sense for an organism that absorbs nutrients from the environment. In other words, a large amount of membrane surface area is available for absorption relative to the volume of the cell that it serves. In addition, most prokaryotes lack the extensive internal organization characteristic of eukaryotes.

## Eukaryotic cells have a nucleus and specialized internal structures.

Eukaryotes are defined by the presence of a nucleus, which houses the vast majority of the cell's DNA. The nuclear membrane allows for more complex regulation of gene expression than is possible in prokaryotic cells ([Chapters 3 and 18](#)). In eukaryotes, DNA is transcribed to RNA inside the nucleus, but the RNA molecules carrying the genetic message travel from inside to outside the nucleus, where they instruct the synthesis of proteins.

Eukaryotes have a remarkable internal array of membranes. These membranes define compartments, called [organelles](#), that divide the cell contents into smaller spaces specialized for different functions. [Fig. 5.17a](#) shows a macrophage, a type of animal cell, with various organelles and their functions. [Fig. 5.17b](#) shows a typical plant cell. In addition to the organelles described in [Fig. 5.17a](#), plant cells have a cell wall outside the plasma membrane, vacuoles specialized for water

uptake, and **chloroplasts** that convert energy of sunlight into chemical energy. Plant cells also have intercellular connections called plasmodesmata, channels that allow the passage of large molecules such as mRNA and proteins between neighboring cells.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 5.17 An animal cell and a plant cell. Animal and plant cells have many cell components in common.

The entire contents of a cell other than the nucleus make up the **cytoplasm**. The jelly-like internal environment of the cell that

surrounds the organelles inside the plasma membrane is referred to as the **cytosol**. In the next two sections, we consider these organelles in more detail, focusing on the role of membranes in forming distinct compartments within the cell.

Self-Assessment Question

10. Compare the organization, degree of compartmentalization, and size of prokaryotic and eukaryotic cells.

## 5.4 THE ENDOMEMBRANE SYSTEM

In eukaryotes, the total surface area of intracellular membranes is about tenfold greater than that of the plasma membrane. This high ratio of internal membrane area to plasma membrane area underscores the significant degree to which a eukaryotic cell is divided into internal compartments. Many of the organelles inside cells are not isolated entities, but instead communicate with one another. In fact, the membranes of these organelles are either physically connected by membrane “bridges” or transiently connected by [vesicles](#), small membrane-enclosed sacs that transport substances within a cell or from the interior to the exterior of the cell. These vesicles form by budding off an organelle, taking with them a piece of the membrane and internal contents of the organelle from which they derive. They then fuse with another organelle or the plasma membrane, re-forming a continuous membrane and unloading their contents.

In total, these interconnected membranes make up the [endomembrane system](#). The endomembrane system includes the nuclear envelope, endoplasmic reticulum, Golgi apparatus, lysosomes, the plasma membrane, and the vesicles that move between them ([Fig. 5.18](#)). In plants, the endomembrane system is actually continuous between cells through plasmodesmata (see [Fig. 5.17](#); [Chapters 10](#) and [26](#)).

Extensive internal membranes are not common in prokaryotic cells. However, photosynthetic bacteria have internal membranes that are specialized for harnessing light energy ([Chapters 8](#) and [25](#)).

## The endomembrane system compartmentalizes the cell.

Because many types of molecules are unable to cross cell membranes on their own, the endomembrane system divides the interior of a cell into two distinct “worlds,” one inside the spaces defined by these membranes and one outside these spaces. A molecule within the interior of the endoplasmic reticulum (ER) can stay in the ER or end up in the interior of the Golgi apparatus or even outside the cell by the

budding off and fusing of a vesicle between these organelles. Similarly, a molecule associated with the ER membrane can move to the Golgi membrane or the plasma membrane by vesicle transport. Molecules in the cytosol are in a different physical space, separated by membranes of the endomembrane system. This physical separation allows specific functions to take place within the spaces defined by the membranes and within the membrane itself.

In spite of forming a continuous and interconnected system, the various compartments have unique properties and maintain distinct identities determined in part by which lipids and proteins are present in their membranes.

Vesicles bud off from and fuse not only with organelles but also with the plasma membrane. When a vesicle fuses with the plasma membrane, the process is called **exocytosis**. It provides a way for a vesicle to empty its contents to the extracellular space or to deliver proteins embedded in the vesicle membrane to the plasma membrane (**Fig. 5.18**). This process also works in reverse: A vesicle can bud off from the plasma membrane, enclosing material from outside the cell and bringing it into the cell interior, in a process called **endocytosis**. Together, exocytosis and endocytosis provide a way to move material into and out of cells without passing through the cell membrane.

## The nucleus houses the genome and is the site of RNA synthesis.

The innermost organelle of the endomembrane system is the nucleus, which stores DNA, the genetic material that encodes the information

for all the activities and structures of the cell. The **nuclear envelope** defines the boundary of the nucleus (**Fig. 5.19**). It actually consists of two membranes, the inner and outer membranes. Each is a lipid bilayer with associated proteins.

The inner and outer membranes are continuous with each other at openings called **nuclear pores**. These large protein complexes allow molecules to move into and out of the nucleus, so they are essential for the nucleus to communicate with the rest of the cell. For example, some proteins that are synthesized in the cytosol, such as transcription factors, move through nuclear pores to enter the nucleus, where they control how and when genetic information is expressed.

In addition, the transfer of information encoded by DNA depends on the movement of mRNA (messenger RNA) molecules out of the nucleus through these pores. After exiting the nucleus, mRNA binds to free ribosomes in the cytosol or ribosomes associated with the endoplasmic reticulum (ER). **Ribosomes** are the sites of protein synthesis, in which amino acids are assembled into polypeptides guided by the information stored in mRNA ([Chapter 4](#)). In this way, the nuclear envelope and its associated protein pores regulate which molecules move into and out of the nucleus.

## The endoplasmic reticulum is involved in protein and lipid synthesis.

The outer membrane of the nuclear envelope is physically continuous with the **endoplasmic reticulum**, an organelle bounded by a single membrane ([Fig. 5.20](#)). The ER is a conspicuous feature of many eukaryotic cells, accounting in some cases for as much as half of the total amount of membrane. The ER produces and transports many of the proteins and lipids used inside and outside the cell, including all transmembrane proteins, as well as proteins destined for the Golgi apparatus, lysosomes, or export out of the cell. The ER is also the site of production of most of the lipids that make up the various internal and external cell membranes.

FIG. 5.20 The endoplasmic reticulum (ER). The ER is a major site for protein and lipid synthesis. Proteins are also synthesized in the cytoplasm.

Unlike the nucleus, which is a single spherical structure in the cell, the ER consists of a complex network of interconnected tubules and flattened sacs. Its interior is continuous throughout and is called the **lumen**. As shown in [Fig. 5.20](#), the ER has an almost mazelike appearance when sliced and viewed in cross section. Its membrane is extensively convoluted, allowing a large amount of membrane surface area to fit within the cell.

When viewed through an electron microscope, ER membranes have two different appearances ([Fig. 5.20](#)). Some look rough because they are studded with ribosomes; this portion of the ER is referred to as

**rough endoplasmic reticulum (RER)**. The rough ER synthesizes transmembrane proteins, proteins that end up in the interior of organelles, and proteins destined for secretion. As a result, cells that secrete large quantities of protein have extensive rough ER, including the cells of the gut that secrete digestive enzymes and the cells of the pancreas that produce insulin. All cells have at least some rough ER for the production of transmembrane and organelle proteins.

A small amount of ER membrane in most cells appears smooth because it lacks ribosomes; this portion of the ER is called **smooth endoplasmic reticulum (SER)** (Fig. 5.20). Smooth ER is the site of fatty acid and phospholipid biosynthesis. Thus, this type of ER predominates in cells specialized for the production of lipids. For example, cells that synthesize steroid hormones have a well-developed SER that produces large quantities of cholesterol. Enzymes within the SER convert cholesterol into steroid hormones.

## The Golgi apparatus modifies and sorts proteins and lipids.

Although it is not physically continuous with the ER, the **Golgi apparatus** is often the next stop for vesicles that bud off the ER. These vesicles carry lipids and proteins, either within the vesicle interior or embedded in their membranes. The movement of these vesicles from the ER to the Golgi apparatus and then to the rest of the cell is part of a biosynthetic pathway in which lipids and proteins are sequentially modified and delivered to their final destinations. The Golgi apparatus has three primary roles: (1) it further modifies proteins and lipids produced by the ER; (2) it acts as a sorting station as these proteins and

lipids move to their final destinations; and (3) it is the site of synthesis of most of the cell's carbohydrates.

Under the microscope, the Golgi apparatus looks like stacks of flattened membrane sacs, called **cisternae**, surrounded by many small vesicles (**Fig. 5.21**). These vesicles transport proteins and lipids from the ER to the Golgi apparatus, and then between the various cisternae, and finally from the Golgi apparatus to the plasma membrane or other organelles. Vesicles are therefore the primary means by which proteins and lipids move through the Golgi apparatus to their final destinations.

Enzymes within the Golgi apparatus chemically modify proteins

and lipids as they pass through it. These modifications take place in a sequence of steps, each performed in a different region of the Golgi apparatus, because each region contains a different set of enzymes that catalyzes specific reactions. As a result, there is a general movement of vesicles from the ER through the Golgi apparatus and then to their final destinations.

An example of a chemical modification that occurs predominantly in the Golgi apparatus is glycosylation, in which sugars are covalently linked to lipids or specific amino acids of proteins, forming glycoproteins. As these lipids and proteins move through the Golgi apparatus, they encounter different enzymes in each region that add or trim sugars. Glycoproteins are important components of the eukaryotic cell surface. The sugars attached to the protein can protect the protein from enzyme digestion by blocking access to the peptide chain. As a result, glycoproteins form a relatively flexible and protective coating over the plasma membrane. The distinctive shapes that sugars contribute to glycoproteins and glycolipids also allow them to be recognized specifically by other cells and molecules in the external environment. For example, human blood types (A, B, AB, and O) are defined by the particular sugars that are linked to proteins and lipids on the surface of red blood cells.

While traffic usually travels from the ER to the Golgi apparatus, a small amount of traffic moves in the reverse direction, from the Golgi apparatus to the ER. This reverse pathway is important to retrieve proteins in the ER or Golgi that were accidentally moved forward and to recycle membrane components.

# Lysosomes degrade macromolecules.

The ability of the Golgi apparatus to sort and dispatch proteins to particular destinations is dramatically illustrated by lysosomes.

**Lysosomes** are specialized vesicles derived from the Golgi apparatus that degrade damaged or unneeded macromolecules ([Fig. 5.22](#)). They contain a variety of enzymes that break down macromolecules such as proteins, nucleic acids, lipids, and complex carbohydrates. The Golgi apparatus packages macromolecules destined for degradation into vesicles. These vesicles then fuse with lysosomes, delivering their contents to the lysosome interior. The Golgi is also responsible for delivering the enzymes that break down macromolecules to the lysosomes.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
Source: Don W. Fawcett/Getty Images.

FIG. 5.22 Lysosomes. Lysosomes are vesicles that degrade macromolecules.

The formation of lysosomes also illustrates the ability of the Golgi apparatus to sort key proteins. The enzymes inside the lysosomes are synthesized in the RER, sorted in the Golgi apparatus, and then packaged into lysosomes. In addition, the Golgi apparatus sorts and delivers specialized proteins that become embedded in lysosomal membranes. These include proton pumps that keep the internal environment at an acidic pH of about 5, the optimal pH for the activity of the enzymes inside. Other proteins in the lysosomal membranes transport the breakdown products of macromolecules, such as amino acids and simple sugars, across the membrane to the cytosol for use by the cell.

The function of lysosomes underscores the importance of having separate compartments within the cell bounded by selectively permeable membranes. Lysosomal enzymes cannot function in the normal cellular environment, which has a pH of about 7, and many of a cell's enzymes and proteins would unfold and degrade if the entire cell were at the pH of the inside of a lysosome. By restricting the activity of these enzymes to the lysosome, the cell protects proteins and organelles in the cytosol from degradation.

## Protein sorting directs proteins to their proper location in or out of the cell.

As we have seen, eukaryotic cells have many compartments, and different proteins function in different places, such as enzymes in

lysosomes or transmembrane proteins embedded in the plasma membrane. **Protein sorting** is the process by which proteins end up where they need to be to perform their function. Protein sorting directs proteins to the cytosol, the lumen of organelles, or the membranes of the endomembrane system, or even out of the cell entirely.

Recall that proteins are produced in two places: free ribosomes in the cytosol and membrane-bound ribosomes on the rough ER. Proteins produced on free ribosomes are sorted after they are translated. These proteins often contain amino acid sequences, called **signal sequences**, that allow them to be recognized and sorted. As shown in **Fig. 5.23**, several types of signal sequences direct proteins synthesized on free ribosomes to different cellular compartments. Proteins with no signal sequence remain in the cytosol (**Fig. 5.23a**). Proteins destined for mitochondria or chloroplasts often have a signal sequence at their amino ends (**Fig. 5.23b**). Proteins targeted to the nucleus usually have signal sequences located internally (**Fig. 5.23c**). These nuclear signal sequences, called **nuclear localization signals**, enable proteins to move through pores in the nuclear envelope.

FIG. 5.23 Signal sequences on proteins synthesized by free ribosomes. (a) Most proteins synthesized by free ribosomes with no signal peptide remain in the cytosol. Other signal sequences direct proteins (b) to mitochondria and chloroplasts or (c) to the nucleus.

In contrast to proteins synthesized by free ribosomes, proteins produced on the rough ER end up in the lumen of the endomembrane system, secreted out of the cell, or as transmembrane proteins ([Fig. 5.24](#)). These proteins are sorted as they are translated.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 5.24 Pathways for proteins destined (left) to be secreted or (right) to be transported to the plasma membrane.

Proteins destined for the ER lumen or secretion have an amino-terminal signal sequence that directs the ribosome to the rough ER ([Fig. 5.25](#)). As a free ribosome translates the protein in the cytosol, this sequence is recognized by an RNA–protein complex known as a [signal-recognition particle \(SRP\)](#). The SRP binds to both the signal sequence and the free ribosome, and brings about a pause in translation ([Fig. 5.25a](#)). The SRP then binds with a receptor on the RER so that the ribosome becomes associated with the RER ([Fig. 5.25b](#)). The SRP receptor brings the ribosome to a channel in the membrane of the RER. The SRP then dissociates and translation continues, allowing the growing polypeptide chain to be threaded through the channel ([Fig. 5.25c](#)). A specific protease cleaves the signal sequence as it emerges in the lumen of the ER ([Fig. 5.25d](#)). Some proteins are retained in the interior of the ER, whereas others are transported in vesicles to the interior of the Golgi apparatus. Some of these proteins are secreted by exocytosis.

FIG. 5.25 Interaction of a signal sequence, signal-recognition particle (SRP),

and SRP receptor. Binding of a signal sequence with the SRP halts translation, followed by docking of the ribosome on the ER membrane, release of the SRP, and continuation of translation.

Proteins destined for cell membranes contain a **signal-anchor sequence** in addition to the amino-terminal signal sequence ([Fig. 5.26](#)). After the growing polypeptide chain and its ribosome are brought to the ER, this complex is threaded through the channel in the ER membrane until the signal-anchor sequence is encountered ([Fig. 5.26a](#)). The signal-anchor sequence is hydrophobic, so it is able to diffuse laterally in the lipid bilayer ([Fig. 5.26b](#)). At this point, the ribosome dissociates from the channel while translation continues. When translation is complete, the amino end of the polypeptide is in the ER lumen, the carboxyl end remains on the cytosolic side of the ER membrane, and the region between them resides in the membrane ([Fig. 5.26c](#)). Transmembrane proteins such as these may stay in the membrane of the ER or end up in other internal membranes or the plasma membrane, where they serve as transporters, pumps, receptors, or enzymes.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 5.26 Targeting of a transmembrane protein by a signal-anchor sequence. Proteins with a hydrophobic signal-anchor sequence end up embedded in the membrane.

### Self-Assessment Questions

11. What are the names and functions of the major organelles of the endomembrane system in eukaryotic cells?
12. How does a protein end up free in the cytosol, embedded in the plasma membrane, or secreted from the cell?

## 5.5 MITOCHONDRIA AND CHLOROPLASTS

The membranes of two organelles, mitochondria and chloroplasts, are not part of the endomembrane system. Both of these organelles are specialized to harness energy for the cell. Interestingly, they are both semi-autonomous organelles that grow and multiply independently of the other membrane-bound compartments, and they contain their own circular genomes. As we discuss in [Chapters 8](#) and [25](#), the similarities between the DNA of these organelles and the DNA of certain bacteria have led scientists to conclude that these organelles originated as bacteria that were captured by another cell and, over time, evolved to their current function.

### Mitochondria provide the eukaryotic cell with most of its usable energy.

[Mitochondria](#) are organelles that harness energy from chemical compounds such as sugars and convert it into ATP, which serves as the universal energy currency of the cell. ATP is able to drive the many chemical reactions in the cell.

Mitochondria are present in nearly all eukaryotic cells. These rod-shaped organelles have an outer membrane and a highly convoluted inner membrane whose folds project into the interior ([Fig. 5.27](#)). A proton electrochemical gradient is generated across the inner mitochondrial membrane, and the energy stored in the gradient is used to synthesize ATP for use by the cell. In the process of breaking down sugar and synthesizing ATP, oxygen is consumed and carbon dioxide

is released.

Does this process sound familiar? It also describes your own breathing, or respiration. Mitochondria are the site of cellular respiration, and the oxygen that you take in with each breath is used by mitochondria to produce ATP. Cellular respiration is discussed in greater detail in [Chapter 7](#).

## Chloroplasts capture energy from sunlight.

Both animal and plant cells have mitochondria to provide them with life-sustaining ATP. In addition, plant cells and green algae have organelles called [chloroplasts](#) that capture the energy of sunlight to

synthesize simple sugars ([Fig. 5.28](#)). This process, called [photosynthesis](#), results in the release of oxygen as a waste product. Like the nucleus and mitochondria, chloroplasts are surrounded by a double membrane. They also have a third, internal membrane, which defines a separate internal compartment called the [thylakoid](#). The thylakoid membrane contains specialized light-collecting molecules called pigments, of which [chlorophyll](#) is the most important. The green color of chlorophyll explains why so many plants have green leaves.

Chlorophyll plays a key role in the chloroplast's ability to capture energy from sunlight. Using the light energy collected by this pigment, enzymes present in the chloroplast use carbon dioxide as a carbon source to produce carbohydrates. Photosynthesis is discussed in greater

detail in [Chapter 8](#).

#### Self-Assessment Questions

13. Are mitochondria present in animal cells, plant cells, or both?
14. What are three similarities between mitochondria and chloroplasts?

## CORE CONCEPTS SUMMARY

**5.1 STRUCTURE OF CELL MEMBRANES:** Cell membranes are composed of lipids, proteins, and carbohydrates.

Phospholipids have both hydrophilic and hydrophobic regions. As a result, they spontaneously form structures such as micelles and bilayers when placed in an aqueous environment. [page 94](#)

Membranes are fluid, meaning that membrane components are able to move laterally in the plane of the membrane. [page 95](#)

Membrane fluidity is influenced by the length of fatty acid chains, the presence of carbon–carbon double bonds in fatty acid chains, and the amount of cholesterol. [page 95](#)

Many membranes also contain proteins that span the membrane (transmembrane proteins) or are temporarily associated with one or other layer of the lipid bilayer (peripheral proteins). [page 97](#)

**5.2 MOVEMENT IN AND OUT OF CELLS:** The plasma membrane is a selective barrier that controls the movement of molecules between the inside and the outside of the cell.

Selective permeability results from the combination of lipids and proteins that makes up cell membranes. [page 99](#)

Passive transport is the movement of molecules by diffusion, the random movement of molecules. There is a net movement of molecules from regions of higher concentration to regions of lower concentration. [page 100](#)

Passive transport can occur by the diffusion of molecules directly through the plasma membrane (simple diffusion) or be aided by protein transporters (facilitated diffusion). [page 100](#)

Active transport moves molecules from regions of lower concentration to regions of higher concentration and requires energy. [page 101](#)

Primary active transport uses energy stored in ATP; secondary active transport uses the energy stored in an electrochemical gradient. [page 101](#)

Animal cells often maintain their size and shape through the actions of protein pumps that actively move ions in and out of the cell. [page 103](#)

Plants, fungi, and bacteria have a cell wall outside the plasma membrane that maintains cell size and shape. [page 103](#)

**5.3 INTERNAL ORGANIZATION OF CELLS:** Cells can be classified as prokaryotes or eukaryotes, which differ in their degree of internal compartmentalization.

Prokaryotic cells lack a nucleus and other internal membrane-enclosed compartments. [page 105](#)

Prokaryotic cells include bacteria and archaeons and are typically much smaller than eukaryotes. [page 105](#)

Eukaryotic cells have a nucleus and other internal compartments called organelles. [page 105](#)

Eukaryotes include animals, plants, fungi, and protists. [page 105](#)

**5.4 THE ENDOMEMBRANE SYSTEM:** The endomembrane system is an interconnected system of membranes that defines spaces in the cell, synthesizes important molecules, and traffics and sorts these molecules in and out of the cell.

The endomembrane system includes the nuclear envelope, endoplasmic reticulum, Golgi apparatus, lysosomes, vesicles, and plasma membrane. [page 107](#)

The nucleus, which is enclosed by a double membrane called the nuclear envelope, houses the genome. [page 108](#)

The endoplasmic reticulum is continuous with the outer nuclear envelope and manufactures proteins and lipids for use by the cell or for export out of the cell. [page 109](#)

The Golgi apparatus communicates with the endoplasmic reticulum by transport vesicles. It receives proteins and lipids from the endoplasmic reticulum and directs them to their final destinations. [page 110](#)

Lysosomes break down macromolecules such as proteins into simpler compounds that can be used by the cell. [page 111](#)

Protein sorting directs proteins to their final destinations inside or outside of the cell. [page 112](#)

Proteins synthesized on free ribosomes are sorted after translation, whereas proteins synthesized on ribosomes associated with the rough endoplasmic reticulum are sorted during translation. [page](#)

[112](#)

Proteins synthesized on free ribosomes are often sorted by means of a signal sequence and are destined for the cytosol, mitochondria, chloroplasts, or nucleus. [page 112](#)

Proteins synthesized on ribosomes on the rough endoplasmic reticulum have a signal sequence that is recognized by a signal-recognition particle. These proteins end up as transmembrane proteins, reside in the interior of various organelles, or are secreted. [page 112](#)

**5.5 MITOCHONDRIA AND CHLOROPLASTS:** Mitochondria and chloroplasts are organelles that harness energy, and likely evolved from free-living prokaryotes.

Mitochondria harness energy from chemical compounds for use by both animal and plant cells. [page 114](#)

Chloroplasts harness the energy of sunlight to build sugars. [page 115](#)

## Chapter 6 Making Life Work

### Capturing and Using Energy

Purestock/Getty Images

---

## CORE CONCEPTS

**6.1 AN OVERVIEW OF METABOLISM:** Metabolism is the set of biochemical reactions that transforms molecules and transfers energy.

**6.2 KINETIC AND POTENTIAL ENERGY:** Kinetic energy is energy of motion, and potential energy is stored energy.

**6.3 LAWS OF THERMODYNAMICS:** The first and second laws of thermodynamics govern energy flow in biological systems.

**6.4 CHEMICAL REACTIONS:** Chemical reactions involve the breaking and forming of bonds.

**6.5 ENZYMES AND THE RATE OF CHEMICAL REACTIONS:** The rate of chemical reactions is increased by protein catalysts called enzymes.

---

We have seen that cells require a way to encode and transmit information and a membrane to separate inside from out. The third requirement of a cell is energy. Cells need energy to do work: to grow and divide, move, change shape, pump ions in and out, transport vesicles, and synthesize macromolecules such as DNA, RNA, proteins, and complex carbohydrates. All of these activities are considered work, and they all require energy.

We are all familiar with different forms of energy—the sun and wind are sources of energy, as are fossil fuels such as oil and natural gas. We have learned to harness the energy from these sources and convert it to other forms, such as electricity, to provide needed power to our homes and cities.

Cells face a similar challenge. They must harness energy from the environment and convert it to a form that allows them to do the work necessary to sustain life. Cells harness energy from the sun and from chemical compounds, including carbohydrates, lipids, and proteins.

Although the source of energy may differ among cells, all cells convert energy to a form that can be easily used to drive cellular processes. All cells use energy in the form of a molecule called [adenosine triphosphate \(ATP\)](#).

ATP is often called the universal “currency” of cellular energy to indicate that ATP provides energy in a form that all cells can readily use to perform work. Although “currency” provides a useful analogy for the role that ATP plays, there is an important distinction between actual currency, such as a dollar bill, and ATP. A dollar bill represents a certain value but does not have any value in itself. By contrast, ATP does not represent energy; it actually contains energy in its chemical bonds. Nevertheless, the analogy is useful because ATP, like a dollar bill, engages in a broad range of energy “transactions” in the cell.

In this chapter, we consider energy in the context of cells. What exactly is energy? What principles govern its flow in biological systems? And how do cells make use of it?

# 6.1 AN OVERVIEW OF METABOLISM

When considering a cell's use of energy, it is helpful to also consider the cell's sources of carbon. Carbon is the backbone of the organic molecules that make up cells and cells often use carbon-based compounds as a stable form of energy storage. How organisms obtain the energy and carbon they need is so fundamental that it is sometimes used to provide a metabolic classification of life ([Fig. 6.1](#)). Simply put, organisms have two ways of harvesting energy from their environment and two sources of carbon. This means that, together, there are four principal ways in which organisms acquire the energy and materials needed to grow, function, and reproduce.

FIG. 6.1 A metabolic classification of organisms. Organisms can be classified

according to their energy and carbon sources.

## Organisms can be classified according to their energy and carbon sources.

Organisms have two ways of harvesting energy from their environment: they can obtain energy either from the sun or from chemical compounds ([Fig. 6.1](#)). Organisms that capture energy from sunlight are called **phototrophs**. Plants are the most familiar example. Plants use the energy of sunlight to convert carbon dioxide and water into sugar and oxygen ([Chapter 8](#)). Sugars, such as glucose, contain energy in their chemical bonds that can be used to synthesize ATP, which in turn can power the work of the cell.

Other organisms derive their energy directly from chemical compounds. These organisms are called **chemotrophs**, and animals are familiar examples. Animals ingest other organisms, obtaining glucose and other organic molecules that they break down in the presence of oxygen to produce carbon dioxide and water. In this process, the energy in the chemical bonds of the organic molecules is converted to energy carried in the bonds of ATP ([Chapter 7](#)).

In drawing this distinction between plants and animals, we have to be careful. Although sunlight provides the energy that plants use to synthesize glucose, plants still power most cellular processes by breaking down the sugar they make, just as animals do. And although animals harness energy from organic molecules, the energy in these organic molecules is generally derived from the sun.

Organisms can also be classified in terms of where they get their carbon ([Fig. 6.1](#)). Some organisms are able to convert carbon dioxide (an inorganic form of carbon) into glucose (an organic form of carbon). These organisms are [autotrophs](#), or “self feeders.” Plants again are an example, so plants are both phototrophs and autotrophs, or photoautotrophs.

Other organisms do not have the ability to convert carbon dioxide into organic forms of carbon. Instead, they obtain their carbon from organic molecules synthesized by other organisms. These organisms eat other organisms or molecules derived from other organisms. Such organisms are [heterotrophs](#), or “other feeders.” Animals obtain carbon in this way, and so animals are both chemotrophs and heterotrophs, or chemoheterotrophs. In fact, animals get their energy and carbon from the same molecule. That is, a molecule of glucose supplies both energy and carbon.

As we explore the diversity of life in [Part 2](#), we will see that not all organisms fit into the two categories of photoautotrophs and chemoheterotrophs ([Fig. 6.1](#)). Some microorganisms gain energy from sunlight but obtain their carbon by ingesting organic molecules; such organisms are called photoheterotrophs. Other microorganisms extract energy from inorganic molecules but build their own organic molecules; these organisms are called chemoautotrophs. They are often found in extreme environments, such as deep-sea vents, where sunlight is absent and inorganic compounds such as hydrogen sulfide are plentiful.

# Metabolism is the set of chemical reactions that sustain life.

The breaking down of organic molecules such as glucose and the harnessing and release of energy in the process are driven by chemical reactions in the cell. The term [metabolism](#) encompasses the entire set of chemical reactions that convert molecules into other molecules and transfer energy in living organisms. These chemical reactions are occurring all the time in your cells. Many of these reactions are linked, in that the products of one are the reactants of the next, forming long pathways and intersecting networks.

Metabolism is divided into two branches: [catabolism](#) is the set of chemical reactions that break down molecules into smaller units and, in the process, produce ATP, and [anabolism](#) is the set of chemical reactions that build molecules from smaller units and require an input of energy, usually in the form of ATP ([Fig. 6.2](#)). For example, carbohydrates can be broken down, or catabolized, into sugars, fats into fatty acids and glycerol, and proteins into amino acids. These initial products can be broken down further to release energy stored in their chemical bonds. By contrast, the synthesis of macromolecules such as carbohydrates and proteins is anabolic.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 6.2 Catabolism and anabolism. The energy harvested as ATP during the breakdown of molecules in catabolism can be used to synthesize molecules in anabolism.

#### Self-Assessment Questions

1. What are the ways that organisms obtain energy and carbon from the environment? What are the names used to describe these organisms?
2. What is the difference between catabolism and anabolism?

## 6.2 KINETIC AND POTENTIAL ENERGY

There are many different sources of energy, including sunlight, wind, electricity, and fossil fuels. The food we eat also contains energy.

**Energy** is important in biological systems because it is needed to do work. A cell is doing work when it carries out the processes we discussed in earlier chapters, such as synthesizing DNA, RNA, and proteins, pumping substances across the plasma membrane, and moving vesicles between various compartments of a cell.

Here, we consider two forms of energy: kinetic energy and potential energy (**Fig. 6.3**). Kinetic energy is energy associated with movement, and potential energy is energy that is stored, for example in the chemical bonds of molecules such as glucose and ATP.

FIG. 6.3 Potential and kinetic energy. Some of the high potential energy of a ball at the top of a set of stairs is transformed to kinetic energy as the ball rolls down the stairs.

## Kinetic energy and potential energy

are two forms of energy.

**Kinetic energy** is the energy of motion, and it is perhaps the most familiar form of energy. A moving object, such as a ball bouncing down a set of stairs, possesses kinetic energy. Kinetic energy is associated with any kind of movement, such as a person running or a muscle contracting. Light, electricity, and thermal energy (perceived as heat) are also forms of kinetic energy, because light is associated with the movement of photons, electricity with the movement of electrons, and thermal energy with the movement of molecules.

Energy is not always associated with motion. An immobile object can still possess a form of energy called **potential energy**, or stored energy. Potential energy depends on the structure of the object or its position relative to a field (gravitational, electrical, magnetic), and it is released by a change in the object's structure or position. For example, the potential energy of a ball is higher at the top of a flight of stairs than at the bottom ([Fig. 6.3](#)). If it were not blocked by the floor, it would move from the position of higher potential energy (the top of the stairs) to the position of lower potential energy (the bottom of the stairs) because of the force of gravity. Similarly, an electrochemical gradient of molecules across a cell membrane is a form of potential energy. Given a pathway through the membrane, the molecules move down their concentration and electrical gradients from higher to lower potential energy ([Chapter 5](#)).

Energy can be converted from one form to another. The ball at the top of the stairs has a certain amount of potential energy because of its position. As it rolls down the stairs, this potential energy is converted

to kinetic energy associated with movement of the ball and the surrounding air. When the ball reaches the bottom of the stairs, the remaining energy is stored as potential energy. Conversely, it takes an input of energy to move the ball back to the top of the stairs, and this input of energy is stored as potential energy.

## Chemical energy is a form of potential energy.

We obtain the energy we need from the food we eat, which contains chemical energy. **Chemical energy** is a form of potential energy held in the chemical bonds between pairs of atoms in a molecule. Recall from [Chapter 2](#) that a covalent bond results from the sharing of electrons between two atoms. Covalent bonds form when the sharing of electrons between two atoms results in a more stable configuration than if they were not shared—that is, than if the orbitals of the two atoms did not overlap.

The more stable configuration will always be the one with lower potential energy. As a result, energy is required to break a covalent bond because going from a lower energy state to a higher one requires an input of energy. Conversely, energy is released when a covalent bond forms.

Some bonds are stronger than other ones. A strong bond is hard to break because the arrangement of orbitals in these molecules is much more stable than if the two atoms do not share electrons. Because strong bonds have a very stable arrangement of orbitals, they do not require a lot of energy to remain intact. As a result, strong bonds do not

contain very much chemical energy, similar to the potential energy of a ball at the bottom of a flight of stairs ([Fig. 6.3](#)). Examples of molecules with strong covalent bonds that contain relatively little chemical energy are carbon dioxide ( $\text{CO}_2$ ) and water ( $\text{H}_2\text{O}$ ).

Conversely, some covalent bonds are relatively weak. These bonds are easily broken because the arrangement of orbitals in these molecules is only somewhat more stable than if the two atoms did not share electrons. As a result, weak covalent bonds require a lot of energy to stay intact and contain a lot of chemical energy, similar to the potential energy of a ball at the top of a flight of stairs ([Fig. 6.3](#)). Organic molecules such as carbohydrates, lipids, and proteins contain relatively weak covalent bonds, including many carbon–carbon ( $\text{C—C}$ ) bonds and carbon–hydrogen ( $\text{C—H}$ ) bonds. Therefore, organic molecules are rich sources of chemical energy and are sometimes called fuel molecules.

## ATP is a readily accessible form of cellular energy.

The chemical energy carried in carbohydrates, lipids, and proteins is harnessed by cells to do work. But cells do not use this energy all at once. Instead, through the series of chemical reactions described in [Chapter 7](#), they package this energy into a chemical form that is readily accessible to the cell. One form of chemical energy is adenosine triphosphate, or ATP, shown in [Fig. 6.4](#). The chemical energy in the bonds of ATP is used in turn to drive many cellular processes, such as muscle contraction, cell movement, and membrane pumps. In this way, ATP serves as a go-between, acting as an intermediary between fuel

molecules that store a large amount of potential energy in their bonds and the activities of the cell that require an input of energy.

FIG. 6.4 The structure of ATP.

The core of ATP is adenosine, which is made up of the base adenine and the five-carbon sugar ribose. To complete the molecule, the ribose is attached to triphosphate, or three phosphate groups ([Fig. 6.4](#)). ATP's chemical relatives are ADP (adenosine diphosphate) and AMP (adenosine monophosphate), with two phosphate groups and one phosphate group, respectively. The use of ATP as an energy source in nearly all cells reflects its use early in the evolution of life on Earth.

The accessible chemical energy of ATP is held in the bonds connecting the phosphate groups. At physiological pH, these phosphate

groups are negatively charged and have a tendency to repel each other. The chemical bonds connecting the phosphate groups therefore contain a lot of chemical energy to keep the phosphate groups connected. This energy is released when new, more stable bonds are formed that contain less chemical energy ([section 6.4](#)). The released energy in turn can be harnessed to power the work of the cell.

#### Self-Assessment Questions

3. What are the two forms of energy? Provide an example of each.
4. What is the relationship between strength of a covalent bond and the amount of chemical energy it contains?
5. Draw the structure of ATP, indicating the bonds that are broken during hydrolysis.

## 6.3 LAWS OF THERMODYNAMICS

Plants and other phototrophs convert energy from the sun into chemical potential energy held in the bonds of molecules. Chemical reactions can transfer this chemical energy between different molecules. And energy from these molecules can be used by the cell to do work. In all these instances, energy is subject to the laws of thermodynamics. In fact, all processes in a cell, from diffusion to osmosis to the pumping of ions to cell movement, are subject to these laws. There are four laws of thermodynamics, but the first and second laws are particularly relevant to biological processes.

### The first law of thermodynamics: energy is conserved.

The [first law of thermodynamics](#) is the law of conservation of energy, which states that the universe contains a constant amount of energy. Therefore, energy is neither created nor destroyed. New energy is never formed, and energy is never lost. Instead, energy changes from one form to another. For example, kinetic energy can change to potential energy and vice versa, but the total amount of energy always remains the same ([Fig. 6.5](#)).

In the simple example of a ball rolling down a set of stairs (see [Fig. 6.3](#)), the potential energy stored at the top of the stairs is converted to kinetic energy associated with the movement of the ball and the surrounding air. The total amount of energy in this transformation is constant—that is, the total potential energy of the ball at the top of the stairs equals the amount of kinetic energy associated with the movement of the ball and air molecules plus the potential energy of the ball at the bottom of the stairs.

## The second law of thermodynamics: energy transformations always result in an increase in disorder in the universe.

When energy changes forms, the total amount of energy remains constant. However, in going from one form of energy to another, the energy available to do work decreases ([Fig. 6.6](#)). How can the total energy remain the same, but the energy available to do work decrease? The answer is that some of the energy is no longer available to do

work. Energy transformations are never 100% efficient because the amount of energy available to do work decreases every time energy changes forms. Thus, there is a universal price to pay in transforming energy from one form to another.

FIG. 6.6 The second law of thermodynamics. Because the amount of disorder increases when energy is transformed from one form to another, some of the total energy is not available to do work.

The energy that is not available to do work takes the form of an increase in disorder. This principle is summarized by the [second law of thermodynamics](#), which states that the transformation of energy is associated with an increase in disorder of the universe. For example, when kinetic energy is changed into potential energy, the amount of disorder always increases. The degree of disorder is called [entropy](#).

The degree of disorder is just one way to describe entropy. Another way to think about entropy is to consider the number of possible positions and motions (collectively called microstates) a molecule can take on in a given system. As entropy increases, so does the number of

positions and motions available to the molecule. Consider the expansion of a gas after the lid is removed from its container. Given more space, the molecules of the gas are less constrained and able to move about more freely. They have more positions available to them and move about at a larger range of speeds, so they have more entropy.

In chemical reactions, most of the entropy increase occurs through the transformation of various forms of energy into thermal energy, which we experience as heat. Thermal energy is a type of kinetic energy corresponding to the random motion of molecules and results in a given temperature. The higher the temperature, the more rapidly the molecules move and the higher the disorder.

Consider the contraction of a muscle, a form of kinetic energy associated with the shortening of muscle cells. The contraction of muscle is powered by chemical potential energy in fuel molecules. Some of this potential energy is transformed into kinetic energy (movement), and the rest is dissipated as thermal energy (which is why your muscles warm as you exercise). Consistent with the first law of thermodynamics, the amount of chemical potential energy expended is equal to the amount of kinetic energy plus the amount of thermal energy. Consistent with the second law, thermal energy flowing as heat is a necessary by-product of the transformation of chemical potential energy into kinetic energy.

In living organisms, catabolic reactions result in an increase of entropy as a single ordered molecule is broken down into several smaller ones with more freedom to move around. Anabolic reactions,

by contrast, might seem to decrease entropy because they use individual building blocks to synthesize more ordered molecules such as proteins or nucleic acids. Do these anabolic reactions violate the second law of thermodynamics? No, because the second law of thermodynamics always applies to the universe as a whole, not to a chemical reaction in isolation. A local decrease in entropy is always accompanied by an even higher increase in the entropy of the surroundings. The production of heat in a chemical reaction increases entropy because heat is associated with the motion of molecules. The combination of the decrease in entropy associated with the building of a macromolecule and the increase in entropy associated with heat always results in a net increase in entropy.

The key point here is that a single cell or a multicellular organism requires a constant input of energy to maintain its high degree of function and organization. This input, as we have seen, comes either from the sun or from the energy stored in chemical compounds. This energy allows molecules to be built and other work to be carried out, but it also leads to greater entropy in the surroundings.

#### Self-Assessment Questions

6. What are the first and second laws of thermodynamics and how do they relate to chemical reactions?
7. Cold air has less entropy than hot air. The second law of thermodynamics states that entropy always increases. Do air conditioners violate this law?

## 6.4 CHEMICAL REACTIONS

Living organisms build and break down molecules, pump ions across membranes, move, and function largely through chemical reactions. As we have seen, organisms break down food molecules, such as glucose, storing energy in the bonds of ATP. That ATP then powers chemical reactions that sustain life. Chemical reactions are therefore central to life processes. In this section, we describe what a chemical reaction is, how the laws of thermodynamics apply to chemical reactions, and how ATP drives many chemical reactions in cells.

### A chemical reaction occurs when molecules interact.

As we saw in [Chapter 2](#), a chemical reaction is the process by which molecules, called reactants, are transformed into other molecules, called products. During a chemical reaction, atoms keep their identity, but the atoms that share bonds change. For example, carbon dioxide ( $\text{CO}_2$ ) and water ( $\text{H}_2\text{O}$ ) can react to produce carbonic acid ( $\text{H}_2\text{CO}_3$ ), as shown in [Fig. 6.7](#).

FIG. 6.7 A chemical reaction. Atoms retain their identity during a chemical reaction as bonds are broken and new bonds are formed to yield new molecules.

This reaction is common in nature. For example, it occurs when carbon dioxide in the air enters ocean waters, and it explains why the oceans are becoming more acidic as carbon dioxide levels in the atmosphere increase. This reaction also takes place in the bloodstream. When cells break down glucose, they produce carbon dioxide. In animals, this carbon dioxide diffuses out of cells and into the blood. Rather than remaining dissolved in solution, most of the carbon dioxide is converted into carbonic acid by the preceding reaction. In an aqueous (watery) environment like the ocean or the blood, carbonic acid exists as bicarbonate ions ( $\text{HCO}_3^-$ ) and protons ( $\text{H}^+$ ).

Many chemical reactions in cells are readily reversible: the products can react to form the reactants. For example, carbon dioxide and water react to form carbonic acid, and carbonic acid can dissociate to produce carbon dioxide and water. This reverse reaction also occurs in the blood, allowing carbon dioxide to be removed from the lungs or gills (Chapter 37). The reversibility of the reaction is indicated by a double arrow ([Fig. 6.7](#)).

The way the reaction is written defines forward and reverse reactions: a forward reaction proceeds from left to right and the reactants are located on the left side of the arrow; a reverse reaction proceeds from right to left and the reactants are located on the right side of the arrow.

The direction of a reaction can be influenced by the concentrations of reactants and products. For example, increasing the concentration of the reactants or decreasing the concentration of the products favors the forward reaction. This effect explains how many reactions in metabolic pathways proceed: the products of many reactions are quickly consumed by the next reaction, helping to drive the first reaction forward.

## The laws of thermodynamics determine whether a chemical reaction requires or releases energy available to do work.

We have seen that cells use chemical reactions to perform much of their work. The amount of energy available to do work is called **Gibbs free energy ( $G$ )**. In a chemical reaction, we can compare the free energy of the reactants and products to determine whether the reaction releases energy that is available to do work. The difference between two values is denoted by the Greek letter delta ( $\Delta$ ). In this case,  $\Delta G$  is the free energy of the products minus the free energy of the reactants (**Fig. 6.8**). If the products of a reaction have more free energy than the reactants, then  $\Delta G$  is positive and a net input of energy is required to drive the reaction forward (**Fig. 6.8a**). By contrast, if the products of a reaction have less free energy than the reactants,  $\Delta G$  is negative and energy is released and available to do work (**Fig. 6.8b**).

FIG. 6.8 Endergonic and exergonic reactions. An endergonic reaction requires an input of energy; an exergonic reaction releases energy.

Reactions with a negative  $\Delta G$  that release energy and proceed spontaneously are called **exergonic**, and reactions with a positive  $\Delta G$  that require an input of energy and are not spontaneous are called **endergonic**. Note that the term “spontaneous” does not imply instantaneous or even rapid. “Spontaneous” in this context means that a reaction releases energy; “non-spontaneous” means that a reaction requires a sustained input of energy.

Recall that the total amount of energy is equal to the energy available to do work plus the energy that is not available to do work because of the increase in entropy. We can write this relationship as an equation in which the total amount of energy is **enthalpy ( $H$ )**, the energy available to do work is Gibbs free energy ( $G$ ), and the energy lost to entropy is **entropy ( $S$ )** multiplied by the **absolute temperature ( $T$ )**, measured in degrees Kelvin), because temperature influences the movement of molecules (and hence the degree of disorder). Therefore,

$$\text{Total amount of energy (H)} = \text{energy available to do work (G)} + \text{energy lost to entropy (TS)}$$

We are interested in the energy available for a cell to do work, or  $G$ . Therefore, we express  $G$  in terms of the other two parameters,  $H$  and  $TS$ , as follows:

$$G = H - TS$$

In a chemical reaction, we can compare the total energy and entropy of the reactants with the total energy and entropy of the products to see if there is energy available to do work. As a result, we get

$$\Delta G = \Delta H - T\Delta S$$

This equation is a useful way to see if a chemical reaction takes place spontaneously and whether net energy is required or released. Let's consider a few examples. The value of  $\Delta G$  depends on both the change in enthalpy and the change in disorder. Consider a reaction in which the products have less chemical energy (lower enthalpy) in their bonds than the reactants have, and the products are more disordered (higher entropy) than the reactants are. This reaction has a negative value of  $\Delta H$  and a positive value of  $\Delta S$ . Notice that, in the equation  $\Delta G = \Delta H - T\Delta S$ , there is a negative sign in front of  $\Delta S$ , so both the negative  $\Delta H$  and positive  $\Delta S$  contribute to a negative  $\Delta G$ . Therefore, this reaction proceeds spontaneously.

Now consider a reaction in which chemical energy increases (positive  $\Delta H$ ) and the degree of disorder decreases (negative  $\Delta S$ ). This reaction has a positive value of  $\Delta G$  and is not spontaneous.

In other cases, the change in enthalpy and the change in entropy are both positive or both negative. In these cases, the absolute values of the energy and enthalpy changes determine whether  $\Delta G$  is positive or negative and therefore whether a reaction is spontaneous or not.

## The hydrolysis of ATP is an exergonic reaction.

Let's apply these concepts to a specific chemical reaction. Earlier, we introduced ATP, the molecule that drives many cellular processes using the chemical potential energy in its chemical bonds. ATP reacts with water to form ADP and inorganic phosphate,  $P_i$  ( $HPO_4^{2-}$ ), as shown here and in [Fig. 6.9](#):

This is an example of a hydrolysis reaction, a chemical reaction in which a water molecule is split into a proton ( $H^+$ ) and a hydroxyl group ( $OH^-$ ). Hydrolysis reactions often break down polymers into their subunits, and in the process one product gains a proton and the other gains a hydroxyl group.

FIG. 6.9 ATP hydrolysis. ATP hydrolysis is an exergonic reaction that releases free energy.

The reaction of ATP with water is an exergonic reaction because there is less free energy in the products than in the reactants. To explain the free energy difference, we can refer to the formula we derived in the last section:

$$\Delta G = \Delta H - T\Delta S$$

Recall that the phosphate groups of ATP are negatively charged at physiological pH and repel each other. ATP has three phosphate groups, and ADP has two. Therefore, ADP is more stable (contains less chemical energy in its bonds) than ATP and the value of  $\Delta H$  is negative. In addition, a single molecule of ATP is broken down into two molecules, ADP and  $P_i$ . Therefore, entropy increases and the value of  $\Delta S$  is positive. Because  $\Delta G = \Delta H - T\Delta S$ ,  $\Delta G$  is negative and the reaction is a spontaneous one that releases energy available to do work.

The free energy difference for ATP hydrolysis is approximately –7.3 kcal per mole (kcal/mol) of ATP. This value is influenced by several factors, including the concentration of reactants and products, the pH of the solution in which the reaction occurs, and the temperature and pressure. The value –7.3 kcal/mol is the value under standard laboratory conditions in which the concentrations of reactants and products are equal and pressure is held constant. In a cell, the free energy difference for ATP hydrolysis is likely higher, on the order of –12 kcal/mol.

The release of free energy during ATP hydrolysis comes from breaking weaker bonds (with more chemical energy) in the reactants and forming more stable bonds (with less chemical energy) in the

products. The release of free energy then drives chemical reactions and other processes that require a net input of energy, as we discuss next.

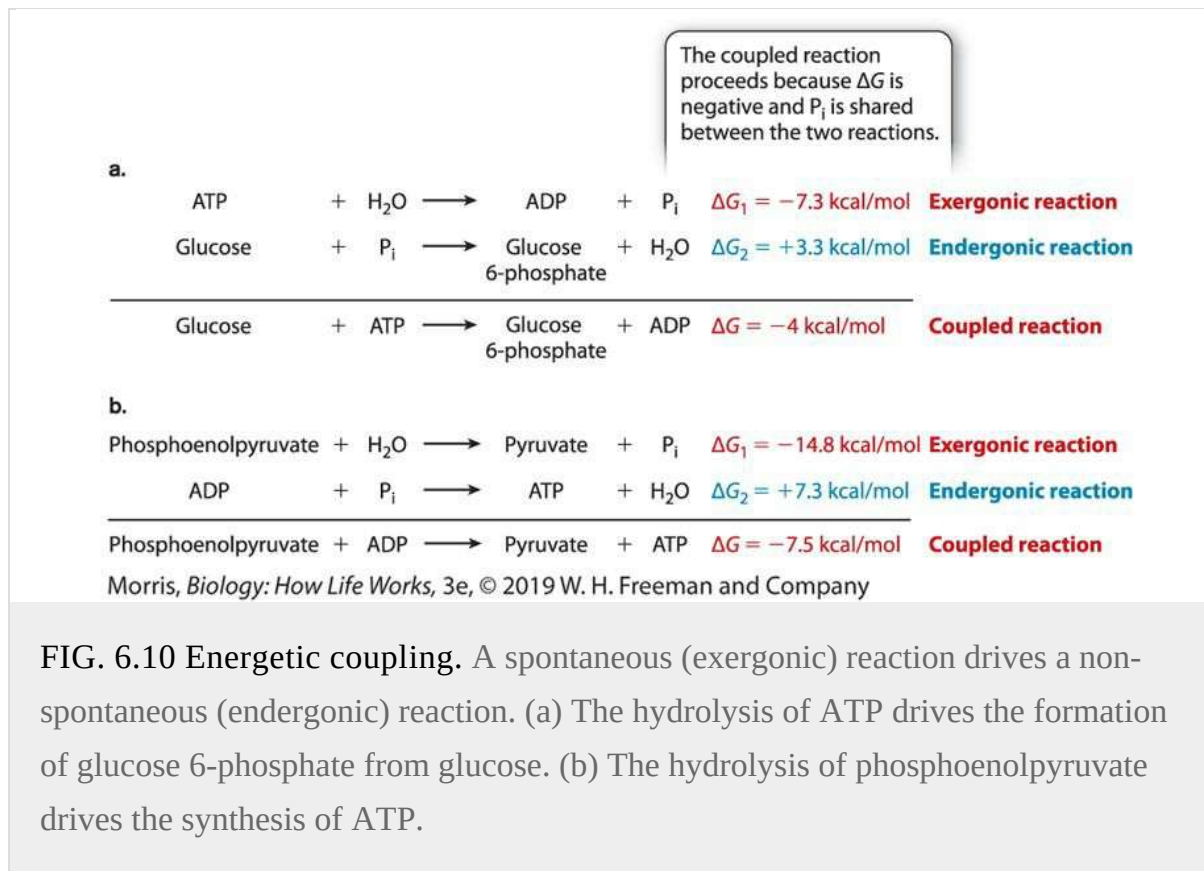

## Non-spontaneous reactions are often coupled to spontaneous reactions.

If the conversion of reactant A into product B is spontaneous, the reverse reaction converting reactant B into product A is not. The  $\Delta G$ 's for the forward and reverse reactions have the same absolute value but opposite signs. In this situation, you might expect that the direction of the reaction would always be from A to B. However, in living organisms, not all chemical reactions are spontaneous. Anabolic reactions are a good example; they require an input of energy to drive them in the right direction. This raises the question: what drives non-spontaneous reactions?

**Energetic coupling** is a process in which a spontaneous reaction (negative  $\Delta G$ ) drives a non-spontaneous reaction (positive  $\Delta G$ ). It requires that the net  $\Delta G$  of the two reactions be negative. In addition, the two reactions must occur together. In some cases, this coupling can be achieved if the two reactions share an intermediate.

For example, a spontaneous reaction, ATP hydrolysis, can be used to drive a non-spontaneous reaction, the addition of a phosphate group to glucose to produce glucose 6-phosphate, as shown in [Fig. 6.10a](#). In this case, the phosphate group transferred to glucose is released during ATP hydrolysis. The net  $\Delta G$  for the two reactions is negative. So ATP hydrolysis provides the thermodynamic driving force for the non-spontaneous reaction, and the shared phosphate group couples the two

reactions together.

Following ATP hydrolysis, the cell needs to replenish its ATP so that it can carry out additional chemical reactions. The synthesis of ATP from ADP and  $P_i$  is an endergonic reaction with a positive  $\Delta G$ , requiring an input of energy. In some cases, exergonic reactions can drive the synthesis of ATP by energetic coupling ([Fig. 6.10b](#)). The sum of the  $\Delta G$ 's of the two reactions is negative and the reactions share a phosphate group, allowing the two reactions to proceed.

Like ATP, other phosphorylated molecules can be hydrolyzed, releasing free energy. Hydrolysis reactions can be ranked by their free energy differences ( $\Delta G$ ). [Fig. 6.11](#) shows that, compared with the hydrolysis of other phosphorylated molecules, ATP hydrolysis has an

intermediate free energy difference. Those reactions that have a  $\Delta G$  more negative than that of ATP hydrolysis transfer a phosphate group to ADP by energetic coupling, and those reactions that have a less negative  $\Delta G$  receive a phosphate group from ATP by energetic coupling. Therefore, ADP is an energy acceptor and ATP an energy donor. The ATP–ADP system is at the core of energetic coupling between catabolic and anabolic reactions.

### Self-Assessment Questions

8. For a chemical reaction with a positive value of  $\Delta G$ , what are the possible relative values for  $\Delta H$  and  $T\Delta S$ ? Is the reaction spontaneous or not? Answer the same questions for a chemical reaction with a negative value of  $\Delta G$ .
9. How does increasing the temperature affect the change in free energy ( $\Delta G$ ) of a chemical reaction?
10. How can the hydrolysis of ATP drive non-spontaneous reactions in a cell?

## 6.5 ENZYMES AND THE RATE OF CHEMICAL REACTIONS

Up to this point, we have focused on the spontaneity and direction of chemical reactions. Now we address their rate. As mentioned earlier, a spontaneous reaction is not necessarily a fast one. For example, the breakdown of glucose into carbon dioxide and water is spontaneous with a negative  $\Delta G$ , but the rate of the reaction is close to zero and the breakdown of glucose is imperceptible. However, glucose is readily broken down inside cells all the time. How is this possible? The answer is that chemical reactions in a cell are accelerated by chemical catalysts.

The rate of a chemical reaction is defined as the amount of product formed (or reactant consumed) per unit of time. Catalysts are substances that increase the rate of chemical reactions without themselves being consumed. In biological systems, the catalysts are usually proteins called **enzymes**, although, as we saw in [Chapter 2](#), some RNA molecules have catalytic activity as well. Enzymes can increase the rate of chemical reactions dramatically. Moreover, because they are highly specific, acting only on certain reactants and catalyzing only some reactions, enzymes play a critical role in determining which chemical reactions take place from all the possible reactions that could occur in a cell. In this section, we discuss how enzymes increase the rate of chemical reactions and how this ability gives them a central role in metabolism.

### Enzymes reduce the activation energy

## of a chemical reaction.

Earlier, we saw that exergonic reactions release free energy and endergonic reactions require free energy. Nevertheless, all chemical reactions require an initial input of energy to proceed, even exergonic reactions that release energy. For an exergonic reaction, the energy released is more than the initial input of energy, so there is a net release of energy.

Why is an input of energy needed for all chemical reactions? As a chemical reaction proceeds, existing chemical bonds break and new bonds form. For an extremely brief period of time, a compound is formed in which the old bonds are breaking and the new ones are forming. This intermediate between reactants and products is called the **transition state**. It is highly unstable and therefore has a large amount of free energy.

In all chemical reactions, reactants adopt at least one transition state before their conversion into products. The graph in **Fig. 6.12** represents the free energy levels of the reactant, transition state, and product. This reaction is spontaneous because the free energy of the reactant is higher than the free energy of the product and  $\Delta G$  is negative. However, the highest free energy value corresponds to the transition state.

FIG. 6.12 An enzyme-catalyzed reaction. An enzyme accelerates a reaction by lowering the activation energy,  $E_A$ .

To reach the transition state, the reactant must absorb energy from its surroundings (the uphill portion of the curve in [Fig. 6.12](#)). As a result, all chemical reactions, even spontaneous ones that release energy, require an input of energy that we can think of as an “energy barrier.” The energy input necessary to reach the transition state is called the **activation energy ( $E_A$ )**. Once the transition state is reached, the reaction proceeds, products are formed, and energy is released into the surroundings (the downhill portion of the curve in [Fig. 6.12](#)). There is an inverse correlation between the rate of a reaction and the height of the energy barrier: the lower the energy barrier, the faster the reaction and the higher the barrier, the slower the reaction.

In chemical reactions that take place in the laboratory, heat is a common source of energy used to overcome the energy barrier. In living organisms, enzymes accelerate chemical reactions. Enzymes do

not act by supplying heat. Instead, they reduce the activation energy by stabilizing the transition state and decreasing its free energy (the red curve in [Fig. 6.12](#)). As the activation energy decreases, the speed of the reaction increases.

Although an enzyme reduces the activation energy, the difference in free energy between reactants and products ( $\Delta G$ ) does not change. In other words, an enzyme changes the path of the reaction between reactants and products, but not the starting or end point ([Fig. 6.12](#)). Consider the breakdown of glucose into carbon dioxide and water. The  $\Delta G$  of the reaction is the same whether it proceeds by combustion or by the action of multiple enzymes in a metabolic pathway in a cell.

## Enzymes form a complex with reactants and products.

As catalysts, enzymes participate in a chemical reaction but are not consumed in the process. They emerge from a chemical reaction unchanged, ready to catalyze the same reaction again. Enzymes accomplish these functions by forming a complex with the reactants and products.

In a chemical reaction catalyzed by an enzyme, the reactant is often referred to as the [substrate](#). In such a reaction, the substrate (S) is converted to a product (P):

In the presence of an enzyme (E), the substrate first forms a complex with the enzyme (enzyme–substrate, or ES). While still part of the

complex, the substrate is converted to product (enzyme–product, or EP). Finally, the complex dissociates, releasing the enzyme and product. Therefore, a reaction catalyzed by an enzyme can be described as

The formation of this complex is critical for accelerating the rate of a chemical reaction. Recall from [Chapter 4](#) that proteins adopt three-dimensional shapes and that the shape of a protein is linked to its function. Enzymes are folded into three-dimensional shapes that bring particular amino acids into close proximity to form an [active site](#). The active site is the part of the enzyme that binds substrate and catalyzes its conversion to the product ([Fig. 6.13](#)). In the active site, the enzyme and substrate form transient covalent bonds, weak noncovalent interactions, or both. Together, these interactions stabilize the transition state and decrease the activation energy.

Enzymes also reduce the energy of activation by positioning two substrates to react: within the active site, their reactive chemical groups are aligned and their motion relative to each other restrained.

The size of the active site is extremely small compared with the size of the enzyme. If only a small fraction of the enzyme is necessary for the catalysis of a reaction, why are enzymes so large? Of the many amino acids that form the active site, only a few actively contribute to catalysis. Each of these amino acids has to occupy a very specific spatial position to align with the correct reactive group on the substrate. If the few essential amino acids were part of a short peptide, the alignment of chemical groups between the peptide and the substrate would be difficult or even impossible because the length of the bonds and the bond angles in the peptide would constrain its three-dimensional structure. In many cases, the catalytic amino acids are spaced far apart in the primary structure of the enzyme, but brought close together by protein folding ([Fig. 6.14](#)). In other words, the large size of many enzymes is required at least in part to bring the catalytic amino acids into very specific positions in the active site of the folded enzyme.

FIG. 6.14 Formation of the active site of an enzyme by protein folding.

The formation of a complex between enzymes and substrates can be demonstrated experimentally, as illustrated in [Fig. 6.15](#).

#### HOW DO WE KNOW?

### FIG. 6.15

## Do enzymes form complexes with substrates?

#### BACKGROUND

The idea that enzymes form complexes with substrates to catalyze a chemical reaction was first proposed in 1888 by the Swedish chemist Svante Arrhenius. In the 1930s, American chemist Kurt Stern performed one of the earliest experiments that supported Arrhenius' idea. Stern studied an enzyme called catalase, which is very abundant in animal and plant tissues. In the conclusion of his paper, he wrote, "It remains to be seen to which extent the findings of this study apply to enzyme action in general." To illustrate that Stern's findings do indeed apply to enzymes in general, another experiment that analyzes a different enzyme and

technique are described here.

Lactose belongs to a family of molecules called  $\beta$ -galactosides. The enzyme  $\beta$ -galactosidase catalyzes the cleavage (splitting) of the glycosidic bond in  $\beta$ -galactoside. In  $\beta$ -thiogalactoside, the oxygen atom in the glycosidic bond is replaced by sulfur. As a result of this difference, the enzyme  $\beta$ -galactosidase binds  $\beta$ -thiogalactoside but cannot cleave or break the glycosidic bond in  $\beta$ -thiogalactoside as it can in  $\beta$ -galactoside.

#### METHOD

A container is separated into two compartments by a selectively permeable membrane. The membrane is permeable to  $\beta$ -galactoside and  $\beta$ -thiogalactoside, but it is not permeable to the enzyme  $\beta$ -galactosidase.

#### EXPERIMENT 1 AND RESULTS

Radioactively labeled  $\beta$ -thiogalactoside (the substrate, S) is added to compartment 1 and the movement of S is followed by measuring the level of radioactivity in the two compartments. Over time, the level of radioactivity becomes the same in the two compartments.

#### EXPERIMENT 2 AND RESULTS

Radioactively labeled  $\beta$ -thiogalactoside (S) is added to compartment 1, the enzyme  $\beta$ -galactosidase (E) is added to compartment 2, and the movement of S is followed by measuring the level of radioactivity in the two compartments. Over time, the level of radioactivity becomes greater in compartment 2 than in compartment 1.

#### INTERPRETATION

The substrate  $\beta$ -thiogalactoside (S) diffuses from compartment 1 to compartment 2, forms a complex (ES) with the enzyme  $\beta$ -galactosidase (E), and is not released because the enzyme (E) does not catalyze the conversion of substrate (S) to product (P). The level of radioactivity is greater in compartment 2 compared to the level in compartment 1 because E and S form a complex (ES) and the radioactive substrate is not released from the complex to diffuse back across the membrane.

SOURCES Adapted from Doherty, D. G., and F. Vaslow. 1952. "Thermodynamic Study of an Enzyme–Substrate Complex of Chymotrypsin." *J. Am. Chem. Soc.* 74:931–936.

## Enzymes are highly specific.

Enzymes are remarkably specific both for the substrate and the reaction that is catalyzed. In general, enzymes recognize either a unique substrate or a class of substrates that share common chemical structures. In addition, enzymes catalyze only one reaction or a very limited number of reactions.

For example, the enzyme succinate dehydrogenase acts only on succinate. Even more remarkably, the enzyme  $\beta$ -(beta-)galactosidase cleaves the glycosidic bond that links galactose to glucose in the disaccharide lactose, but it does not cleave an almost identical molecule that differs from lactose only in the orientation of the glycosidic bond. In this case, the enzyme does not recognize the whole substrate but a particular structural motif within it, and very small differences in the structure of this motif affect the activity of the enzyme. The specificity of enzymes can be attributed to the structure of

their active sites. The active site interacts only with substrates having a precise three-dimensional structure.

## Enzyme activity can be influenced by inhibitors and activators.

The activity of enzymes can be influenced by [inhibitors](#) and [activators](#). Inhibitors decrease the activity of enzymes, whereas activators increase the activity of enzymes. Enzyme inhibitors are quite common. They are synthesized naturally by many plants and animals as a defense against predators. Similarly, pesticides and herbicides often target enzymes to inactivate them. Many drugs used in medicine are enzyme inhibitors, including drugs used to treat infections as well as drugs used to treat cancer and other diseases. Given the importance of chemical reactions and the role of enzymes in metabolism, it is not surprising that enzyme inhibitors have such widespread applications.

There are two classes of inhibitors. Irreversible inhibitors usually form covalent bonds with enzymes and irreversibly inactivate them. Reversible inhibitors form weak bonds with enzymes and therefore easily dissociate from them.

Inhibitors can act in many different ways, two of which are shown in [Fig. 6.16](#). In some cases, an inhibitor is similar in structure to the substrate and therefore is able to bind to the active site of the enzyme ([Fig. 6.16a](#)). Binding of the inhibitor prevents the binding of the substrate. In other words, the inhibitor competes with the substrate for the active site of the enzyme. These types of inhibitors can often be overcome by increasing the concentration of substrate. Other inhibitors

bind to a site other than the active site of the enzyme but still inhibit the activity of the enzyme ([Fig. 6.16b](#)). In this case, binding of the inhibitor changes the shape and therefore the activity of the enzyme. This type of inhibitor usually has a structure very different from that of the substrate.

FIG. 6.16 Two mechanisms of inhibitor function. (a) Some inhibitors bind to the active site of the enzyme and (b) other inhibitors bind to a site that is different from the active site. Both types of inhibitor reduce the activity of an enzyme and therefore decrease the rate of the reaction.

**Allosteric enzymes regulate key metabolic pathways.**

Enzymes that are regulated by molecules that bind at sites other than their active sites are called **allosteric enzymes**. The activity of allosteric enzymes can be influenced by both inhibitors and activators. They play a key role in the regulation of metabolic pathways. Consider the synthesis of isoleucine from threonine, a pathway found in some bacteria. This conversion requires five reactions, each catalyzed by a different enzyme (**Fig. 6.17**).

FIG. 6.17 Regulation of threonine dehydratase, an allosteric enzyme. The enzyme is inhibited by the final product, isoleucine, which binds to a site distinct from the active site.

Once the bacterium has enough isoleucine for its needs, it would be

a waste of energy to continue synthesizing the amino acid. To shut down the pathway once it is no longer needed, the cell relies on an enzyme inhibitor. The inhibitor is isoleucine, the final product of the five reactions. Isoleucine binds to the first enzyme in the pathway, threonine dehydratase, at a site distinct from the active site. Threonine dehydratase is thus an example of an allosteric enzyme. The binding of isoleucine changes the shape of the enzyme and in this way inhibits its function.

The isoleucine pathway provides an example of [negative feedback](#), in which the final product inhibits the first step of the reaction. This is a common mechanism used widely in organisms to maintain homeostasis—that is, to actively maintain stable conditions or steady levels of a substance ([Chapter 5](#)).

The activity of threonine dehydratase, and therefore the rate of the reaction, depends on the concentration of substrate. At a low concentration of threonine, the rate of the reaction is very slow. As the concentration of threonine increases, the activity of the enzyme increases. At a particular threshold, a small increase in threonine concentration results in a large increase in reaction rate. Finally, when there is excess substrate, the reaction rate slows down.

In the next two chapters, we examine more closely two key metabolic processes, cellular respiration and photosynthesis. Both of these processes require many chemical reactions acting in a coordinated fashion. Allosteric enzymes catalyze key reactions in these and other metabolic pathways. These enzymes are usually found at or

near the start of a metabolic pathway or at the crossroads between two metabolic pathways. Allosteric enzymes are one way that the cell coordinates the activity of multiple metabolic pathways.

---

## CASE 1 LIFE'S ORIGINS: INFORMATION, HOMEOSTASIS, AND ENERGY

### What naturally occurring elements might have spurred the first reactions that led to life?

Many enzymes contain metal ions in addition to amino acids. These ions are one type of **cofactor**, a substance that associates with an enzyme and plays a key role in its function. Metallic cofactors, especially iron, magnesium, manganese, cobalt, copper, zinc, and molybdenum, bind to diverse proteins, including enzymes used in DNA synthesis and nitrogen metabolism. With this in mind, scientists have asked whether metal ions might, by themselves, catalyze chemical reactions thought to have played a role in the origin of life. They do. For example, magnesium and zinc ions added to solutions can accelerate the linking of nucleotides to form RNA and DNA molecules.

Metallic cofactors also bind to enzymes used in the transport of electrons for cellular respiration and photosynthesis, as discussed in the next two chapters. Some particularly important enzymes used for electron transport contain iron and sulfur clustered together. Iron–

sulfur minerals, especially pyrite (or fool's gold,  $\text{FeS}_2$ ), form commonly in mid-ocean hydrothermal vent systems and other environments where oxygen is absent. It has been proposed that reactions now carried out in cells by iron–sulfur proteins are the evolutionary descendants of chemical reactions that took place spontaneously on the early Earth.

The idea that your cells preserve an evolutionary memory of ancient hydrothermal environments may seem like science fiction, but it finds support in laboratory experiments. For example, the reaction of  $\text{H}_2\text{S}$  and  $\text{FeS}$  to form pyrite has been shown to catalyze a number of plausibly pre-biotic chemical reactions, including the formation of pyruvate (a key intermediate in energy metabolism discussed in [Chapter 7](#)). Thus, the metals in enzymes help connect the chemistry of life to the chemistry of Earth.

#### Self-Assessment Questions

11. What are three characteristics of enzymes, and how does each permit chemical reactions to occur in cells?
12. Which of the following do enzymes change?  $\Delta G$ , reaction rate, types of product, activation energy, the laws of thermodynamics.
13. How does protein folding allow for enzyme specificity?

## CORE CONCEPTS SUMMARY

**6.1 AN OVERVIEW OF METABOLISM:** Metabolism is the set of biochemical reactions that transforms molecules and transfers energy.

Organisms can be grouped according to their source of energy: phototrophs obtain energy from sunlight and chemotrophs obtain energy from chemical compounds. [page 119](#)

Organisms can also be grouped according to the source of carbon they use to build organic molecules: heterotrophs obtain carbon from organic molecules, and autotrophs obtain carbon from inorganic sources, such as carbon dioxide. [page 120](#)

Catabolism is the set of chemical reactions that break down molecules and release energy, and anabolism is the set of chemical reactions that build molecules and require energy. [page 121](#)

**6.2 KINETIC AND POTENTIAL ENERGY:** Kinetic energy is energy of motion and potential energy is stored energy.

Kinetic energy is energy associated with movement. [page 121](#)

Potential energy is stored energy; it depends on the structure of an object or its position relative to its surroundings. [page 122](#)

Chemical energy is a form of potential energy held in the bonds of molecules. [page 122](#)

The bonds linking phosphate groups in ATP have high potential energy that can be harnessed for use by the cell. [page 122](#)

**6.3 LAWS OF THERMODYNAMICS:** The first and second laws of thermodynamics govern energy flow in biological systems.

The first law of thermodynamics states that energy cannot be created or destroyed. [page 123](#)

The second law of thermodynamics states that there is an increase in entropy in the universe over time. [page 123](#)

**6.4 CHEMICAL REACTIONS:** Chemical reactions involve the breaking and forming of bonds.

In a chemical reaction, atoms themselves do not change, but which atoms are linked to each other changes, forming new molecules. [page 124](#)

The direction of a chemical reaction is influenced by the concentration of reactants and products. [page 125](#)

Gibbs free energy ( $G$ ) is the amount of energy available to do work. [page 125](#)

Three thermodynamic parameters define a chemical reaction: Gibbs free energy ( $G$ ), enthalpy ( $H$ ), and entropy ( $S$ ). [page 125](#)

Exergonic reactions are spontaneous ( $\Delta G < 0$ ) and release energy. [page 125](#)

Endergonic reactions are non-spontaneous ( $\Delta G > 0$ ) and require energy. [page 125](#)

The change of free energy in a chemical reaction is described by  $\Delta G = \Delta H - T\Delta S$ . [page 125](#)

The hydrolysis of ATP is an exergonic reaction that drives many endergonic reactions in a cell. [page 126](#)

In living systems, non-spontaneous reactions are often coupled to spontaneous ones. [page 127](#)

## **6.5 ENZYMES AND THE RATE OF CHEMICAL REACTIONS:**

The rate of chemical reactions is increased by protein catalysts called enzymes.

Enzymes reduce the free energy level of the transition state between reactants and products, thereby reducing the energy input, or activation energy, required for a chemical reaction to proceed. [page 128](#)

During catalysis, the substrate and product form a complex with the enzyme. Transient covalent bonds, weak noncovalent interactions, or both stabilize the complex. [page 128](#)

The size of the active site of an enzyme is small compared to the size of the enzyme as a whole and the active site amino acids occupy a very specific spatial arrangement. [page 128](#)

An enzyme is highly specific for its substrate and for the types of reaction it catalyzes. [page 129](#)

Inhibitors reduce the activity of enzymes and can act irreversibly or reversibly. [page 129](#)

Activators increase the activity of enzymes. [page 129](#)

Allosteric enzymes bind activators and inhibitors at sites other than

the active site, resulting in a change in their shape and activity.

[page 129](#)

Allosteric enzymes are often found at or near the start of a metabolic pathway or at the crossroads of multiple pathways. [page 130](#)

# CHAPTER 7 Cellular Respiration

## Harvesting Energy from Carbohydrates and Other Fuel Molecules

Steve Satushek/Getty Images

---

### CORE CONCEPTS

#### **7.1 AN OVERVIEW OF CELLULAR RESPIRATION:** Cellular

respiration is a series of catabolic reactions that converts the energy in fuel molecules into energy in ATP.

**7.2 GLYCOLYSIS:** Glycolysis is the partial oxidation of glucose and results in the production of pyruvate, as well as ATP and reduced electron carriers.

**7.3 PYRUVATE OXIDATION:** Pyruvate is oxidized to acetyl-CoA, connecting glycolysis to the citric acid cycle.

**7.4 THE CITRIC ACID CYCLE:** The citric acid cycle results in the complete oxidation of fuel molecules and the generation of ATP and reduced electron carriers.

**7.5 THE ELECTRON TRANSPORT CHAIN AND OXIDATIVE PHOSPHORYLATION:** The electron transport chain transfers electrons from electron carriers to oxygen, using the energy released to pump protons and synthesize ATP by oxidative phosphorylation.

**7.6 ANAEROBIC METABOLISM:** Glucose can be broken down in the absence of oxygen by fermentation, producing a modest amount of ATP.

**7.7 METABOLIC INTEGRATION:** Metabolic pathways are integrated, allowing control of the energy level of cells.

---

All living organisms have the ability to harness energy from the environment. We saw in [Chapter 6](#) that energy is needed for all kinds of functions, including cell movement and division, muscle contraction, growth and development, and the synthesis of macromolecules. Organic molecules such as carbohydrates, lipids, and proteins are good sources of chemical energy. Some organisms, such as humans and other heterotrophs, consume organic molecules in their

diet. Others, such as plants and other autotrophs, synthesize these molecules from inorganic molecules such as carbon dioxide.

Regardless of how they obtain organic molecules, nearly all organisms—animals, plants, fungi, and microbes—break them down in the process of **cellular respiration**, releasing energy that can be used to do the work of the cell. Cellular respiration is a series of chemical reactions that convert the chemical energy in fuel molecules into the chemical energy of **adenosine triphosphate (ATP)**. ATP can be readily used as a source of energy by all cells.

It is tempting to think that organic molecules are converted into energy in this process, but this is not the case. Recall from [Chapter 6](#) that the first law of thermodynamics states that energy cannot be created or destroyed. Rather than creating energy, cellular respiration converts energy from one form to another. Specifically, it converts the chemical potential energy stored in organic molecules to the chemical potential energy in ATP.

It is also easy to forget that organisms other than animals, such as plants, use cellular respiration. If plants use sunlight as a source of energy, why would they need cellular respiration? As we will see in the next chapter, plants use the energy of sunlight to make carbohydrates. Plants then break down these carbohydrates in the process of cellular respiration to produce ATP.

In this chapter, we discuss the metabolic pathways of cellular respiration that supply the energy needs of a cell: the breakdown, storage, and mobilization of sugars such as glucose, the synthesis of

ATP, and the coordination and regulation of these metabolic pathways.

# 7.1 AN OVERVIEW OF CELLULAR RESPIRATION

In [Chapter 6](#), we saw that catabolism describes the set of chemical reactions that breaks down molecules into smaller units. In the process, these reactions release chemical energy that can be stored in molecules of ATP. Anabolism, by contrast, is the set of chemical reactions that build molecules from smaller units. Anabolic reactions require an input of energy, usually in the form of ATP.

Cellular respiration is one of the major sets of catabolic reactions in a cell. During cellular respiration, fuel molecules such as glucose, fatty acids, and proteins are catabolized into smaller units, releasing the energy stored in their chemical bonds to power the work of the cell.

**Cellular respiration uses chemical energy stored in molecules such as carbohydrates and lipids to produce ATP.**

Cellular respiration is a series of catabolic reactions that converts the energy stored in food molecules, such as glucose, into the energy stored in ATP and that produces carbon dioxide as a waste or by-product. Cellular respiration can occur in the presence of oxygen (termed aerobic respiration) or in its absence (termed anaerobic respiration). Most organisms that you are familiar with are capable of aerobic respiration; some bacteria respire anaerobically (Chapter 24). Here we focus on aerobic respiration. Oxygen is consumed in aerobic

respiration, and carbon dioxide and water are produced:

In [Chapter 6](#), we saw that molecules such as carbohydrates and lipids have a large amount of potential energy in their chemical bonds. In contrast, molecules such as carbon dioxide and water have less potential energy in their bonds. Cellular respiration releases a large amount of energy because the sum of the potential energy in all of the chemical bonds of the reactants (glucose and oxygen) is higher than that of the products (carbon dioxide and water). The maximum amount of free energy—energy available to do work—released during cellular respiration is  $-686$  kcal per mole of glucose. Recall from [Chapter 6](#) that when  $\Delta G < 0$ , energy is released.

The overall reaction for cellular respiration helps us focus on the starting reactants, final products, and release of energy. However, it misses the many intermediate steps. Tossing a match into the gas tank of a car releases a tremendous amount of energy in the form of an explosion, but this energy is not used to do work. Instead, it is released as light and heat. Similarly, if all the energy stored in glucose were released at once, most of it would be released as heat and the cell would not be able to harness it to do work.

In cellular respiration, energy is released gradually in a series of chemical reactions ([Fig. 7.1](#)). As a result, some of this energy can be used to form ATP. On average, 32 molecules of ATP are produced from the aerobic respiration of a single molecule of glucose. The energy needed to form one mole of ATP from ADP and  $\text{P}_i$  is at least

7.3 kcal. Thus, cellular respiration harnesses at least  $32 \times 7.3 = 233.6$  kcal of energy in ATP for every mole of glucose that is broken down in the presence of oxygen.

FIG. 7.1 An overview of cellular respiration. In most organisms, cellular respiration consumes oxygen and produces ATP by substrate-level phosphorylation and oxidative phosphorylation, as well as carbon dioxide and water.

About 34% of the total energy released by aerobic respiration is harnessed in the form of ATP ( $233.6/686 = 34\%$ ), with the remainder of the energy given off as heat. This degree of efficiency compares favorably with the approximately 25% efficiency of a gasoline engine.

**ATP is generated by substrate-level phosphorylation and oxidative phosphorylation.**

In cellular respiration, ATP is produced in two ways ([Fig. 7.1](#)). In the first, an organic molecule transfers a phosphate group directly to ADP, as we saw in [Chapter 6](#). In this case, a single enzyme carries out two coupled reactions: the hydrolysis of an organic molecule to yield a phosphate group and the addition of that phosphate group to ADP. The hydrolysis reaction releases enough free energy to drive the synthesis of ATP. This way of generating ATP is called **[substrate-level phosphorylation](#)** because a phosphate group is transferred to ADP from an enzyme substrate, in this case an organic molecule.

Substrate-level phosphorylation produces only a small amount of the total ATP generated in cellular respiration, about 12% if the fuel molecule is glucose. The remaining 88% is produced by **[oxidative phosphorylation](#)** ([Fig. 7.1](#)). In this case, the chemical energy of organic molecules is transferred first to **[electron carriers](#)**. The role of these electron carriers is exactly what their name suggests—they carry electrons (and energy) from one set of reactions to another. In cellular respiration, electron carriers transport electrons released during the catabolism of organic molecules to the respiratory **[electron transport chain](#)**. Electron transport chains in turn transfer electrons along a series of membrane-associated proteins to a final electron acceptor and in the process, harness the energy released to produce ATP. In aerobic respiration, oxygen is the final electron acceptor, resulting in the formation of water. Electron transport chains are central to the energy economy of most cells. In respiration, electron transport chains harness energy from fuel molecules such as glucose, and in photosynthesis they harness energy from sunlight ([Chapter 8](#)). In [section 7.5](#), we discuss how electron movement through the electron transport chain is coupled

to ATP synthesis.

## Redox reactions play a central role in cellular respiration.

Chemical reactions in which electrons are transferred from one atom or molecule to another are called **oxidation–reduction reactions** (“redox reactions” for short). Oxidation is the loss of electrons, and reduction is the gain of electrons. The loss and gain of electrons always occur together in a coupled oxidation–reduction reaction: electrons are transferred from one molecule to another so that one molecule loses electrons and one molecule gains those electrons. The molecule that loses electrons is oxidized and the molecule that gains electrons is reduced.

We can illustrate oxidation–reduction reactions by looking at the role played by electron carriers in cellular respiration. Two important electron carriers are nicotinamide adenine dinucleotide and flavin adenine dinucleotide. These electron carriers exist in two forms—an oxidized form ( $\text{NAD}^+$  and FAD) and a reduced form (NADH and  $\text{FADH}_2$ ). When fuel molecules such as glucose are catabolized, some of the steps are oxidation reactions. These oxidation reactions are coupled with the reduction of electron carrier molecules. These reduction reactions can be written as:

Here,  $\text{NAD}^+$  and FAD accept electrons and are converted to their

reduced forms, NADH and FADH<sub>2</sub>. Note that in redox reactions involving organic molecules such as NAD<sup>+</sup> or FAD, the gain (or loss) of electrons is often accompanied by the gain (or loss) of protons (H<sup>+</sup>). Therefore, you can easily recognize reduced molecules by an increase in C—H bonds and the corresponding oxidized molecules by a decrease in C—H bonds.

In their reduced forms, NADH and FADH<sub>2</sub> can donate electrons. As they are oxidized to NAD<sup>+</sup> and FAD, they transfer electrons (and energy) to the electron transport chain:

NAD<sup>+</sup> and FAD can then accept electrons from the breakdown of fuel molecules. In this way, electron carriers act as shuttles, transferring electrons derived from the oxidation of fuel molecules such as glucose to the electron transport chain.

Cellular respiration can itself be understood as a redox reaction, even though it consists of many steps. In aerobic respiration, glucose is oxidized, releasing carbon dioxide, and at the same time oxygen is reduced, forming water:

Let's first consider the oxidation reaction ([Fig. 7.2a](#)). In glucose, there are many C—C and C—H covalent bonds, in which electrons are shared about equally between the two atoms. By contrast, in carbon dioxide, electrons are not shared equally. The oxygen atom is more electronegative than the carbon atom, so the electrons are more likely to be found near the oxygen atom. As a result, carbon has partially lost electrons to oxygen and is oxidized.

a. Oxidation

b. Reduction

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 7.2 Oxidation and reduction in the overall reaction for cellular respiration. Electrons are partially lost or gained in the formation of polar covalent bonds.

Let's now consider the reduction reaction ([Fig. 7.2b](#)). In oxygen gas, electrons are shared equally between two oxygen atoms. In water, the electrons that are shared between hydrogen and oxygen are more likely to be found near oxygen because oxygen is more electronegative than hydrogen. As a result, oxygen has partially gained electrons and is

reduced.

## Cellular respiration occurs in four stages.

Up to this point, we have focused on the overall reaction of cellular respiration and the chemistry of redox reactions. Let's now look at the entire process, starting with glucose. Cellular respiration occurs in four stages ([Fig. 7.3](#)).

FIG. 7.3 The four stages of cellular respiration. Cellular respiration consists of glycolysis, pyruvate oxidation, the citric acid cycle, and oxidative phosphorylation.

In stage 1, glucose is partially broken down to produce pyruvate, and energy is transferred to ATP and reduced electron carriers, a process known as **glycolysis**.

In stage 2, pyruvate is oxidized to another molecule called acetyl-coenzyme A (acetyl-CoA), producing reduced electron carriers and releasing carbon dioxide.

Acetyl-CoA enters stage 3, the **citric acid cycle**, also called the tricarboxylic (TCA) cycle or the Krebs cycle. In this series of chemical reactions, the acetyl group is completely oxidized to carbon dioxide and energy is transferred to ATP and reduced electron carriers. The amount of energy transferred to ATP and reduced electron carriers in this stage is nearly twice that transferred by stages 1 and 2 combined.

Stage 4 is **oxidative phosphorylation**. In this series of reactions, reduced electron carriers generated in stages 1–3 donate electrons to the electron transport chain and a large amount of ATP is produced.

Each stage of cellular respiration consists of a series of reactions, some of which are redox reactions. Therefore, glucose is not oxidized all at once to carbon dioxide. Instead, it is oxidized slowly and in a controlled manner, allowing for energy to be harnessed. Some of this energy is used to synthesize ATP directly and some of it is stored temporarily in reduced electron carriers and then used to generate ATP by oxidative phosphorylation.

**Fig. 7.4** shows the change of free energy at each step in the catabolism of glucose. As you can see, the individual reactions allow the initial chemical energy present in a molecule of glucose to be “packaged” into molecules of ATP and reduced electron carriers. Note that the change in free energy is much greater for the steps that

generate reduced electron carriers than for those that produce ATP directly.

FIG. 7.4 Change in free energy in cellular respiration. Glucose is oxidized through a series of chemical reactions, releasing energy in the form of ATP and reduced electron carriers.

In eukaryotes, glycolysis takes place in the cytoplasm, and pyruvate oxidation, the citric acid cycle, and oxidative phosphorylation all take place in mitochondria. The electron transport chain is made up of proteins and small molecules associated with the inner mitochondrial membrane ([Chapter 5](#)). In some bacteria, these reactions take place in the cytoplasm, and the electron transport chain is located in the plasma membrane.

#### Self-Assessment Questions

1. What are the four major stages of cellular respiration? Briefly

describe each one.

2. What is an oxidation–reduction reaction? Why is the breakdown of glucose in the presence of oxygen to produce carbon dioxide and water an example of an oxidation–reduction reaction?
3. For each of the following pairs of molecules, indicate which member of the pair is reduced and which is oxidized, and which has more chemical energy and which has less chemical energy:  $\text{NAD}^+/\text{NADH}$ ;  $\text{FAD}/\text{FADH}_2$ ;  $\text{CO}_2/\text{C}_6\text{H}_{12}\text{O}_6$ .
4. What are two different ways in which ATP is generated in cellular respiration?

## 7.2 GLYCOLYSIS

Glucose is the most common fuel molecule in animals, plants, and microbes. It is the starting molecule for glycolysis, which results in the partial oxidation of glucose and the synthesis of a relatively small amount of both ATP and reduced electron carriers. Glycolysis literally means “splitting sugar,” an apt name because a 6-carbon sugar (glucose) is split in two in this process, yielding two 3-carbon molecules. Glycolysis is anaerobic because oxygen is not consumed. It evolved very early in the evolution of life, when oxygen was not present in Earth’s atmosphere. It occurs in nearly all living organisms and is therefore probably the most widespread metabolic pathway among organisms.

### Glycolysis is the partial breakdown of glucose.

Glycolysis begins with a molecule of glucose and produces two 3-carbon molecules of pyruvate and a net total of two molecules of ATP and two molecules of the electron carrier NADH. ATP is produced directly by substrate-level phosphorylation.

Glycolysis is a series of 10 chemical reactions ([Fig. 7.5](#)). These reactions can be divided into three phases.

FIG. 7.5 Glycolysis. Glucose is partially oxidized to pyruvate, with the net production of two ATP and two NADH.

The first phase prepares glucose for the next two phases by the addition of two phosphate groups to glucose. This phase requires an input of energy. To supply that energy and provide the phosphate

groups, two molecules of ATP are hydrolyzed per molecule of glucose. In other words, the first phase of glycolysis is an endergonic process. The phosphorylation of glucose has two important consequences. Whereas glucose enters and exits cells through specific membrane transporters, phosphorylated glucose is trapped inside the cell. In addition, the presence of two negatively charged phosphate groups in proximity destabilizes the molecule so that it can be broken apart in the second phase of glycolysis.

The second phase is the cleavage phase, in which the 6-carbon molecule is split into two 3-carbon molecules. For each molecule of glucose entering glycolysis, two 3-carbon molecules enter the third phase of glycolysis.

The third and final phase of glycolysis is sometimes called the payoff phase because ATP and the electron carrier NADH are produced. Later, NADH will contribute to the synthesis of ATP during oxidative phosphorylation. This phase ends with the production of two molecules of pyruvate.

In summary, glycolysis begins with a single molecule of glucose (six carbons) and produces two molecules of pyruvate (three carbons each). These reactions yield four molecules of ATP and two molecules of NADH. However, two ATP molecules are consumed during the initial phase of glycolysis, resulting in a net gain of two ATP molecules and two molecules of NADH ([Fig. 7.5](#)).

5. What is the overall chemical equation for glycolysis?
6. At the end of glycolysis, but before the subsequent stages in cellular respiration, which molecules contain some of the chemical energy held in the original glucose molecule?

## 7.3 PYRUVATE OXIDATION

Glycolysis occurs in almost all living organisms, but it does not generate very much energy in the form of ATP. The end product, pyruvate, still contains a good deal of chemical potential energy in its bonds. In the presence of oxygen, pyruvate can be further oxidized to release more energy, first to acetyl-CoA and then even further in the series of reactions in the citric acid cycle. Pyruvate oxidation to acetyl-CoA is a key step that links glycolysis to the citric acid cycle.

### The oxidation of pyruvate connects glycolysis to the citric acid cycle.

In eukaryotes, pyruvate oxidation is the first step that takes place inside the mitochondria. Mitochondria are rod-shaped organelles surrounded by a double membrane ([Fig. 7.6](#); [Chapter 5](#)). The inner membrane has folds that project inward. These membranes define two spaces: the space between the inner and outer membranes is called the [intermembrane space](#), and the space enclosed by the inner membrane is called the [mitochondrial matrix](#).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 7.6 Mitochondrial membranes and compartments.

Pyruvate is transported into the mitochondrial matrix, where it is converted into acetyl-CoA ([Fig. 7.7](#)). First, part of the pyruvate molecule is oxidized and splits off to form carbon dioxide, the most oxidized (and therefore the least energetic) form of carbon. The electrons lost in this process are donated to  $\text{NAD}^+$ , which is reduced to NADH. The remaining part of the pyruvate molecule, an acetyl group ( $\text{COCH}_3$ ), still contains a large amount of potential energy. It is transferred to coenzyme A (CoA), a molecule that carries the acetyl group to the next set of reactions.

FIG. 7.7 Pyruvate oxidation. Pyruvate is oxidized in the mitochondrial matrix, forming acetyl-CoA, the first substrate in the citric acid cycle.

Overall, the synthesis of one molecule of acetyl-CoA from pyruvate results in the formation of one molecule of carbon dioxide and one molecule of NADH. Recall, however, that a single molecule of glucose forms two molecules of pyruvate during glycolysis. Therefore, two molecules of carbon dioxide, two molecules of NADH, and two molecules of acetyl-CoA are produced from a single glucose molecule in this stage of cellular respiration. Acetyl-CoA is the substrate of the first step in the citric acid cycle.

#### Self-Assessment Question

- At the end of pyruvate oxidation, but before the subsequent stages of cellular respiration, which molecules contain the energy held in the original glucose molecule?

## 7.4 THE CITRIC ACID CYCLE

During the citric acid cycle, fuel molecules are completely oxidized. Specifically, the acetyl group of acetyl-CoA is completely oxidized to carbon dioxide and the chemical energy is transferred to ATP by substrate-level phosphorylation and to the reduced electron carriers NADH and FADH<sub>2</sub>. In this way, the citric acid cycle supplies electrons to the electron transport chain, leading to the production of much more energy in the form of ATP than is obtained by glycolysis alone.

### The citric acid cycle produces ATP and reduced electron carriers.

Like the synthesis of acetyl-CoA, the citric acid cycle takes place in the mitochondrial matrix. It is composed of eight reactions and is called a cycle because the starting molecule, oxaloacetate, is regenerated at the end ([Fig. 7.8](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 7.8 The citric acid cycle. The acetyl group of acetyl-CoA is completely oxidized, with the net production of one ATP, three NADH, and one  $\text{FADH}_2$ .

In the first reaction, the 2-carbon acetyl group of acetyl-CoA is transferred to a 4-carbon molecule of oxaloacetate to form the 6-carbon molecule citric acid or tricarboxylic acid (hence the alternative names “citric acid cycle” and “tricarboxylic acid cycle”). The molecule of citric acid is then oxidized in a series of reactions. The last reaction of the cycle regenerates a molecule of oxaloacetate, which can join to a new acetyl group and allow the cycle to continue.

The citric acid cycle results in the complete oxidation of the acetyl group of acetyl-CoA. Because the first reaction creates a molecule with six carbons and the last reaction regenerates a 4-carbon molecule, two carbons are eliminated during the cycle. These carbons are released as carbon dioxide. Along with the release of carbon dioxide from pyruvate during pyruvate oxidation, these reactions are the sources of carbon dioxide released during cellular respiration and therefore the sources of the carbon dioxide that we exhale when we breathe.

Four redox reactions, including the two that release carbon dioxide, produce the reduced electron carriers NADH and  $\text{FADH}_2$ . In this way, energy released in the oxidation reactions is transferred to a large quantity of reduced electron carriers: three molecules of NADH and one molecule of  $\text{FADH}_2$  per turn of the cycle. These electron carriers donate electrons to the electron transport chain.

A single substrate-level phosphorylation reaction generates a molecule of GTP ([Fig. 7.8](#)). GTP can transfer its terminal phosphate to a molecule of ADP to form ATP.

Overall, two molecules of acetyl-CoA produced from a single molecule of glucose yield two molecules of ATP, six molecules of NADH, and two molecules of  $\text{FADH}_2$  in the citric acid cycle.

CASE 1 LIFE'S ORIGINS: INFORMATION,  
HOMEOSTASIS, AND ENERGY

## What were the earliest energy-harnessing reactions?

Some bacteria run the citric acid cycle in reverse, incorporating carbon dioxide into organic molecules instead of liberating it. Running the citric acid cycle in reverse requires energy, which is supplied by sunlight ([Chapter 8](#)) or chemical reactions (Chapter 24).

Why would an organism run the citric acid cycle backward? The answer is that running the cycle in reverse allows an organism to build, rather than break down, organic molecules. Whether the cycle is run in the reverse or forward direction, the intermediates generated step by step as the cycle turns provide the building blocks for synthesizing the cell's key organic molecules ([Fig. 7.9](#)). Pyruvate, for example, is the starting point for the synthesis of sugars and the amino acid alanine; acetate is the starting point for the synthesis of the cell's lipids; oxaloacetate is modified to form different amino acids and pyrimidine bases; and  $\alpha$ -(alpha)-ketoglutarate is modified to form other amino acids.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 7.9 Molecules produced by the citric acid cycle. Many organic molecules can be synthesized from citric acid cycle intermediates.

Therefore, for organisms that run the cycle in the forward direction, the citric acid cycle is used to generate both energy-storing molecules (ATP and reduced electron carriers) and intermediates in the synthesis of other molecules. For organisms that run the cycle in reverse, it is used to generate intermediates in the synthesis of other molecules and also to incorporate carbon into organic molecules.

The citric acid cycle is thus central to both the synthesis of organic molecules and to meeting the energy requirements of cells, suggesting that it evolved early in some of the first cells to feature metabolism.

The early appearance of the citric acid cycle, in turn, implies that the great variety of biosynthetic and energy-yielding pathways found in modern cells evolved through the extension and modification of this deeply rooted cycle. As typical of evolution, new cellular capabilities arose by the modification of simpler, more general sets of reactions.

Self-Assessment Question

8. At the end of the citric acid cycle, but before the subsequent stages of cellular respiration, which molecules contain the energy held in the original glucose molecule?

## 7.5 THE ELECTRON TRANSPORT CHAIN AND OXIDATIVE PHOSPHORYLATION

The complete oxidation of glucose during the first three stages of cellular respiration results in the production of two kinds of reduced electron carriers: NADH and FADH<sub>2</sub>. We are now going to see how the energy stored in these electron carriers is used to synthesize ATP.

The energy in these electron carriers is released in a series of redox reactions that occur as electrons pass through a chain of protein complexes in the inner mitochondrial membrane to the final electron acceptor, oxygen, which is reduced to water. The energy released by these redox reactions is not converted directly into the chemical energy of ATP, however. Instead, the passage of electrons is coupled to the transfer of protons (H<sup>+</sup>) across the inner mitochondrial membrane, creating a concentration and charge gradient ([Chapter 5](#)). This electrochemical gradient provides a source of potential energy that is then used to drive the synthesis of ATP.

We next explore the properties of the electron transport chain, the role of the proton gradient, and the synthesis of ATP.

### The electron transport chain transfers electrons and pumps protons.

The electron transport chain is made up of four large protein

complexes (known as complexes I to IV) that are embedded in the inner mitochondrial membrane ([Fig. 7.10](#)). The inner mitochondrial membrane contains one of the highest concentrations of proteins found in eukaryotic membranes.

FIG. 7.10 The electron transport chain. (a) The electron transport chain consists

of four complexes (I to IV) in the inner mitochondrial membrane. (b) Electrons flow from electron carriers to oxygen, the final electron acceptor. (c) The proton gradient formed from the electron transport chain has potential energy that is used to synthesize ATP.

Electrons donated by NADH and FADH<sub>2</sub> are transported along this series of protein complexes. Electrons enter the electron transport chain at either complex I or II. Electrons donated by NADH enter through complex I, and electrons donated by FADH<sub>2</sub> enter through complex II. (Complex II is the same enzyme that catalyzes step 6 in the citric acid cycle.) These electrons are transported through either complex I or II to complex III and then through complex IV.

Within each protein complex of the electron transport chain, electrons are passed from electron donors to electron acceptors. Each donor and acceptor is a redox couple, consisting of an oxidized and a reduced form of a molecule. The electron transport chain contains many of these redox couples. When oxygen accepts electrons at the end of the electron transport chain, it is reduced to form water:

This reaction is catalyzed by complex IV.

Electrons also must be transported between the four complexes ([Fig. 7.10](#)). **Coenzyme Q (CoQ)**, also called ubiquinone, accepts electrons from both complexes I and II. In this reaction, two electrons and two protons are transferred to CoQ from the mitochondrial matrix, forming CoQH<sub>2</sub>. Once formed, CoQH<sub>2</sub> diffuses in the inner membrane to

complex III. In complex III, electrons are transferred from  $\text{CoQH}_2$  to [cytochrome c](#) and protons are released into the intermembrane space. When it accepts an electron, cytochrome *c* is reduced, diffuses in the intermembrane space, and passes the electron to complex IV.

The electron transfer steps within complexes are each associated with the release of energy. Some of this energy is used to reduce the next electron acceptor in the chain, but in complexes I, III, and IV, some of it is used to pump protons ( $\text{H}^+$ ) across the inner mitochondrial membrane, from the mitochondrial matrix to the intermembrane space ([Fig. 7.10](#)). Thus, the transfer of electrons through complexes I, III, and IV is coupled with the pumping of protons. The result is an accumulation of protons in the intermembrane space.

## The proton gradient is a source of potential energy.

Like all membranes, the inner mitochondrial membrane is selectively permeable: protons cannot passively diffuse across this membrane, and the movement of other molecules is controlled by transporters and channels ([Chapter 5](#)). We have just seen that the movement of electrons through membrane-embedded protein complexes is coupled to the pumping of protons from the mitochondrial matrix into the intermembrane space. The result is a proton gradient, a difference in proton concentration across the inner membrane.

The proton gradient has two components: a chemical gradient that results from the difference in concentration and an electrical gradient that results from the difference in charge between the two sides of the

membrane. To reflect the dual contribution of the two gradients, the proton gradient is also called an electrochemical gradient.

The proton gradient is a source of potential energy, as discussed in [Chapters 5](#) and [6](#). It stores energy in much the same way that a battery or a dam does. Protons in this gradient have a high concentration in the intermembrane space and a low concentration in the mitochondrial matrix. As a result, there is a tendency for protons to diffuse back to the mitochondrial matrix, driven by a difference in concentration and charge on the two sides of the membrane. This movement, however, is blocked by the membrane. The gradient stores potential energy because, if a pathway is opened through the membrane, the resulting movement of the protons through the membrane can be used to perform work.

In sum, the oxidation of the electron carriers NADH and FADH<sub>2</sub> leads to the generation of a proton electrochemical gradient. This gradient is a source of potential energy used to synthesize ATP.

## ATP synthase converts the energy of the proton gradient into the energy of ATP.

In 1961, Peter Mitchell proposed a hypothesis to explain how the energy stored in the proton electrochemical gradient is used to synthesize ATP. In 1978, he was awarded the Nobel Prize in Chemistry for work that fundamentally changed the way we understand how a cell harnesses energy.

According to Mitchell's hypothesis, the gradient of protons provides a source of potential energy that is converted into chemical energy stored in ATP. First, for the potential energy of the proton gradient to be released, there must be an opening in the membrane for the protons to flow through. Mitchell suggested that protons in the intermembrane space diffuse down their electrical and concentration gradients through a transmembrane protein channel into the mitochondrial matrix. Second, the movement of protons through the channel must be coupled with the synthesis of ATP. This coupling is made possible by **ATP synthase**, an enzyme composed of two distinct subunits called  $F_o$  and  $F_1$  (**Fig. 7.11**).  $F_o$  forms the channel in the inner mitochondrial membrane through which protons flow;  $F_1$  is the catalytic unit that synthesizes ATP. Proton flow through the channel makes it possible for the enzyme to synthesize ATP.

FIG. 7.11 ATP synthase. ATP synthase drives the synthesis of ATP by means of an electrochemical proton gradient.

Proton flow through the  $F_o$  channel causes it to rotate, converting the energy of the proton gradient into mechanical rotational energy, a form of kinetic energy. The rotation of the  $F_o$  subunit leads to rotation of the  $F_1$  subunit in the mitochondrial matrix ([Fig. 7.11](#)). The rotation of the  $F_1$  subunit in turn causes conformational changes that allow it to catalyze the synthesis of ATP from ADP and  $P_i$ . In this way, mechanical rotational energy is converted into the chemical energy of ATP.

Direct experimental evidence for Mitchell's idea, called the [chemiosmotic hypothesis](#), did not come for over a decade. One of the key experiments that provided support for his idea is illustrated in [Fig. 7.12](#).

#### HOW DO WE KNOW?

### FIG. 7.12

## Can a proton gradient drive the synthesis of ATP?

#### BACKGROUND

Peter Mitchell's hypothesis that a proton gradient can drive the synthesis of ATP was met with skepticism because he proposed the idea before experimental evidence existed to support it. In the 1970s, biochemist Efraim Racker and his collaborator Walther Stoeckenius tested the hypothesis.

## EXPERIMENT

Racker and StoECKenius built an artificial system consisting of a collection of vesicle-shaped membranes, each with ATP synthase and a bacterial proton pump that was activated by light.

They measured the concentration of protons (pH) in the external medium and the amount of ATP produced in the presence and absence of light.

## RESULTS

In the presence of light, the pH of the external medium increased. An increase in pH indicates a decrease in concentration of protons as a result of movement of protons from the outside to the inside of the vesicles. This result demonstrates that the proton pump was activated and the vesicles were taking up protons. In the dark, the pH returned to the starting level.

Morris, *Biology: How Life Works*, 3e,  
© 2019 W. H. Freeman and Company

Furthermore, ATP was generated in the light, but not in the dark.

| CONDITION | RELATIVE LEVEL OF ATP |
|-----------|-----------------------|
| Light     | 594                   |
| Dark      | 23                    |

#### INTERPRETATION

In the presence of light, the proton pump was activated and protons were pumped to one side of the membrane, leading to the formation of a proton gradient. The proton gradient, in turn, powered synthesis of ATP by ATP synthase.

#### CONCLUSION

A membrane, proton gradient, and ATP synthase are sufficient to synthesize ATP. This result provided experimental evidence for Mitchell's hypothesis.

Approximately 2.5 molecules of ATP are produced for each NADH that donates electrons to the chain and 1.5 molecules of ATP for each  $\text{FADH}_2$ . Overall, the complete oxidation of glucose yields about 32 molecules of ATP from all four stages of cellular respiration ([Table 7.1](#)). Some of the energy held in the bonds of glucose is now available in a molecule that can be readily used by cells.

**TABLE 7.1** Approximate Total ATP Yield in Cellular Respiration

| PATHWAY                                                       | SUBSTRATE-LEVEL<br>PHOSPHORYLATION | OXIDATIVE<br>PHOSPHORYLATION                 | TOTAL<br>ATP |

| Total                                                         | 4 ATP                              | 28 ATP                                       | 32           |

It is worth taking a moment to follow the flow of energy in cellular respiration, illustrated in its full form in [Fig. 7.13](#). We began with glucose and noted that it holds chemical potential energy in its covalent bonds. This energy is released in a series of reactions and captured in chemical form. Some of these reactions generate ATP directly by substrate-level phosphorylation. Others are redox reactions that transfer energy to the electron carriers NADH and  $\text{FADH}_2$ . These electron carriers donate electrons to the electron transport chain.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 7.13 The flow of energy in cellular respiration. A single glucose molecule yields 32 ATP molecules.

The electron transport chain uses the energy stored in the electron carriers to pump protons across the inner membrane of the mitochondria. In other words, the energy of the reduced electron carriers is transformed into energy stored in a proton electrochemical gradient. ATP synthase then converts the energy of the proton gradient to rotational energy, which drives the synthesis of ATP. The cell now has a form of energy that it can use in many ways to perform work.

#### Self-Assessment Questions

9. Animals breathe in air that contains more oxygen than the air they breathe out. Where is oxygen consumed?
10. How does the movement of electrons along the electron transport chain lead to the generation of a proton gradient?
11. How is a proton gradient used to generate ATP?
12. Uncoupling agents are proteins spanning the inner mitochondrial membrane that allow protons to pass through the membrane and bypass the channel of ATP synthase. Describe the consequences for the proton gradient and ATP production.

## 7.6 ANAEROBIC METABOLISM

Up to this point, we have followed a single metabolic path: the breakdown of glucose in the presence of oxygen to produce carbon dioxide and water. However, metabolic pathways more often resemble intersecting roads rather than a single, linear path. As an example, we saw earlier that intermediates of the citric acid cycle often feed into other metabolic pathways.

One of the major forks in the metabolic road occurs at pyruvate, the end product of glycolysis ([section 10.2](#)). When oxygen is present, it is converted to acetyl-CoA, which then enters the citric acid cycle. When oxygen is not present, pyruvate is metabolized along a number of different pathways. These pathways occur in many living organisms today and played an important role in the early evolution of life on Earth.

### Fermentation extracts energy from glucose in the absence of oxygen.

Pyruvate has many possible fates in the cell. In the absence of oxygen, it can be broken down by [fermentation](#), a process for extracting energy from fuel molecules that does not rely on oxygen or an electron transport chain, but instead uses an organic molecule as an electron acceptor. Fermentation is accomplished through a wide variety of metabolic pathways. These pathways are important for anaerobic organisms that live without oxygen, as well as yeast and some other organisms that favor fermentation over oxidative phosphorylation,

even in the presence of oxygen. Aerobic organisms sometimes use fermentation when oxygen cannot be delivered fast enough to meet the cell's metabolic needs, as in exercising muscle.

Recall that during glycolysis, glucose is oxidized to form pyruvate and  $\text{NAD}^+$  is reduced to form NADH. For glycolysis to continue, NADH must be oxidized to  $\text{NAD}^+$ ; otherwise, glycolysis would grind to a halt. In the presence of oxygen,  $\text{NAD}^+$  is regenerated when NADH donates its electrons to the electron transport chain. In the absence of oxygen during fermentation, NADH is oxidized to  $\text{NAD}^+$  when pyruvate or a derivative of pyruvate is reduced.

Two of the major fermentation pathways are [lactic acid fermentation](#) and [ethanol fermentation](#) ([Fig. 7.14](#)). Lactic acid fermentation occurs in animals and bacteria. During lactic acid fermentation, electrons from NADH are transferred to pyruvate to produce lactic acid and  $\text{NAD}^+$  ([Fig. 7.14a](#)). The overall chemical reaction is written as follows:

a. Lactic acid fermentation

b. Ethanol fermentation

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 7.14 Lactic acid and ethanol fermentation pathways.

Ethanol fermentation occurs in plants and fungi. During ethanol fermentation, pyruvate releases carbon dioxide to form acetaldehyde, and electrons from NADH are transferred to acetaldehyde to produce ethanol and NAD<sup>+</sup> ([Fig. 7.14b](#)). The overall chemical reaction is written as follows:

In both fermentation pathways, NADH is oxidized to NAD<sup>+</sup>. However, NADH and NAD<sup>+</sup> do not appear in the overall chemical equations because there is no net production or loss of either molecule. NAD<sup>+</sup> molecules that are reduced during glycolysis are oxidized when lactic acid or ethanol is formed.

The breakdown of a molecule of glucose by fermentation yields only two molecules of ATP. The energetic gain is relatively small compared with the yield of aerobic respiration because the end products, lactic acid and ethanol, are not fully oxidized and still contain a large amount of chemical energy in their bonds. Organisms that produce ATP by fermentation therefore must consume a large quantity of fuel molecules to power the cell.

CASE 1 LIFE'S ORIGINS: INFORMATION,  
HOMEOSTASIS, AND ENERGY

# How did early cells meet their energy requirements?

The four stages of cellular respiration lead to the full oxidation of glucose and the release of a large amount of energy stored in its chemical bonds. In the first stage, glycolysis, glucose is only partially oxidized, so just some of the energy held in its chemical bonds is released. Nearly all organisms are capable of partially breaking down glucose, suggesting that glycolysis evolved very early in the history of life.

The atmosphere contained no oxygen when life first evolved about 4 billion years ago. The earliest organisms probably used one of the fermentation pathways to generate ATP. Fermentation occurs in the cytoplasm, does not require atmospheric oxygen, and does not require proteins embedded in specialized membranes.

As we have seen, cellular respiration makes use of an electron transport chain, composed of proteins embedded in a membrane and capable of transferring electrons from one protein to the next and pumping protons. The resulting proton gradient powers the synthesis of ATP. Like fermentation, cellular respiration can occur in the absence of oxygen, but in that case molecules other than oxygen, such as sulfate and nitrate, are the final electron acceptor (Chapter 26). This form of respiration is known as anaerobic respiration and occurs in some present-day bacteria. The electron transport chain in these bacteria is located in the plasma membrane, not in an internal membrane.

How might such a system have evolved? An intriguing possibility is

that early prokaryotes evolved pumps to drive protons out of the cell in response to an increasingly acidic environment ([Fig. 7.15](#)). Some pumps might have used the energy of ATP to pump protons, while others used the energy from electron transport to pump protons ([Fig. 7.15a](#)). At some point, proton pumps powered by electron transport might have generated a large enough electrochemical gradient that the protons could pass back through the ATP-driven pumps, running them in reverse to synthesize ATP ([Fig. 7.15b](#)).

FIG. 7.15 The possible evolution of the electron transport chain and oxidative phosphorylation.

Organisms capable of producing oxygen, the cyanobacteria, did not evolve until about 2.5 billion years ago, or maybe earlier. The evolution of this new form of life introduced oxygen into Earth's atmosphere. This dramatic change led to the evolution of new life-

forms with new possibilities for extracting energy from fuel molecules such as glucose. Aerobic respiration, in which oxygen serves as the final electron acceptor in the electron transport chain, generates much more energy than does anaerobic respiration or fermentation.

The evolution of cellular respiration illustrates that evolution often works in a stepwise fashion, building on what is already present. In this case, aerobic respiration picked up where anaerobic respiration left off, making it possible to harness more energy from organic molecules to power the work of the cell.

#### Self-Assessment Questions

13. Bread making involves ethanol fermentation and typically uses yeast, sugar, flour, and water. Why are yeast and sugar used?
14. What are two different metabolic pathways that pyruvate can enter?

## 7.7 METABOLIC INTEGRATION

In this chapter, we have focused on the breakdown of glucose. What happens if there is more glucose than the cell needs? As well as glucose, organisms consume diverse carbohydrates, lipids, and proteins. How are these broken down? And how are the various metabolic pathways that break down fuel molecules coordinated so that the intracellular level of ATP is maintained in a narrow range? In this final section, we consider how the cell responds to these challenges.

### Excess glucose is stored as glycogen in animals and starch in plants.

Glucose is a readily available form of energy in organisms, but it is not always broken down immediately. Excess glucose can be stored in cells and then mobilized when necessary. Glucose can be stored in two major forms: as **glycogen** in animals and as **starch** in plants (**Fig. 7.16**). Both these molecules are large branched polymers of glucose.

FIG. 7.16 Storage forms of glucose. (a) Glycogen is a storage form of glucose in animal cells, and (b) starch is a storage form of glucose in plant cells.

Carbohydrates in the diet are broken down into glucose and other simple sugars and circulate in the blood. The level of glucose in the blood is tightly regulated (Chapter 37). When the blood glucose level is high, as it is after a meal, glucose molecules that are not consumed by glycolysis are linked together to form glycogen in liver and muscle. Glycogen stored in muscle is used to provide ATP for muscle contraction. By contrast, the liver does not store glycogen primarily for its own use, but is a glycogen storehouse for the whole body. Glucose molecules located at the end of glycogen chains can be cleaved one by one and released in the form of glucose 1-phosphate. Glucose 1-phosphate is converted into glucose 6-phosphate, an intermediate in glycolysis (see [Fig. 7.5](#)). One glucose molecule cleaved off a glycogen chain produces three and not two molecules of ATP by glycolysis because the ATP-consuming step 1 of glycolysis is bypassed.

## Sugars other than glucose contribute to glycolysis.

The carbohydrates in your diet are digested to produce a variety of sugars. Some of these are disaccharides (maltose, lactose, and sucrose) with two sugar units; others are monosaccharides (fructose, mannose, and galactose) with one sugar unit ([Fig. 7.17](#)). The disaccharides are hydrolyzed into monosaccharides, which are transported into cells.

FIG. 7.17 Common sugars in the diet.

Glucose molecules released during digestion directly enter glycolysis. What happens to other sugars? They, too, enter glycolysis, although not as glucose. Instead, they are converted into intermediates of glycolysis that come later in the pathway ([Fig. 7.18](#)). For example, fructose is produced by the hydrolysis of sucrose (table sugar) and receives a phosphate group to form either fructose 6-phosphate or fructose 1-phosphate. In the liver, fructose 1-phosphate is cleaved and converted into glyceraldehyde 3-phosphate, which enters glycolysis at reaction 6 (see [Fig. 7.5](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 7.18 Other fuel molecules. Sugars other than glucose, fats such as triacylglycerol, and proteins are all fuel molecules that are broken down and enter the cellular respiration pathway at different places.

## Fatty acids and proteins are useful sources of energy.

We know from common experience that lipids are also a good source of energy. Butter, oils, ice cream, and the like all contain lipids and are high in calories, which are units of energy. We can also infer that lipids

are a good source of energy from their chemical structure. Recall from [Chapter 2](#) that a type of fat called triacylglycerol is composed of three fatty acid molecules bound to a glycerol backbone (see [Fig. 2.25](#)). These fatty acid molecules are rich in carbon–carbon and carbon–hydrogen bonds, which, as we saw earlier, carry chemical potential energy.

Following a meal, the small intestine very quickly absorbs triacylglycerols, which are then transported by the bloodstream and either consumed or stored in fat (adipose) tissue. Triacylglycerols are broken down inside cells to glycerol and fatty acids ([Fig. 7.18](#)). Then, the fatty acids themselves are shortened by a series of reactions that sequentially remove two carbon units from their ends. This process is called  [\*\*\$\beta\$ -\(beta\)-oxidation\*\*](#). It does not generate ATP, but produces NADH and FADH<sub>2</sub> molecules that provide electrons for the synthesis of ATP by oxidative phosphorylation. In addition, the end product of the reaction is acetyl-CoA, which feeds the citric acid cycle and leads to the production of additional reduced electron carriers.

The oxidation of fatty acids produces a large amount of ATP. For example, the complete oxidation of a molecule of palmitic acid, a fatty acid containing 16 carbons, yields about 106 molecules of ATP. By contrast, glycolysis yields just 2 molecules of ATP, and the complete oxidation of a glucose molecule produces about 32 molecules of ATP ([Table 7.1](#)). Fatty acids therefore are a useful and efficient source of energy, but they cannot be used by all tissues of the body. Notably, the brain and red blood cells depend primarily on glucose for energy.

Proteins, like fatty acids, are a source of chemical energy that can be broken down, if necessary, to power the cell. Proteins are typically first broken down to amino acids, which enter at various points in glycolysis, pyruvate oxidation, and the citric acid cycle ([Fig. 7.18](#)).

## The intracellular level of ATP is a key regulator of cellular respiration.

ATP is the key end product of cellular respiration. ATP is constantly being turned over in a cell, broken down to ADP and  $P_i$  to supply the cell's energy needs, and re-synthesized by fermentation and cellular respiration. The level of ATP inside a cell can therefore be an indicator of how much energy a cell has available. When ATP levels are high, the cell has a high amount of free energy and is poised to carry out cellular processes. In this case, pathways that generate ATP are slowed, or down-regulated. By contrast, when ATP levels are low, pathways that generate ATP are activated, or up-regulated. Other intermediates of cellular respiration, such as NADH, have a similar effect in that high  $NAD^+$  levels stimulate cellular respiration, whereas high NADH levels inhibit it ([Fig. 7.19](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 7.19 Regulation of cellular respiration. Cellular respiration is inhibited by its products, including ATP and NADH, and activated by its substrates, including ADP and NAD<sup>+</sup>.

How is this kind of coordinated response of the cell possible? The cell uses several mechanisms, one of which is the regulation of enzymes that control key steps of the pathway. One of these key reactions is reaction 3 of glycolysis. In this reaction, fructose 6-phosphate is converted to fructose 1,6-bisphosphate, and a molecule of ATP is consumed. This is a key step in glycolysis because it is highly endergonic and irreversible. As a result, it is considered a “committed” step and is subject to tight control. This reaction is catalyzed by the enzyme phosphofructokinase-1 (PFK-1). You can think of this enzyme as a metabolic valve that regulates the rate of glycolysis.

PFK-1 is an allosteric enzyme with many activators and inhibitors (**Fig. 7.20**). Recall from [Chapter 6](#) that an allosteric enzyme changes its shape and activity in response to the binding of molecules at a site other than the active site. ADP and AMP are allosteric activators of PFK-1. When ADP and AMP are abundant, one or the other binds to the enzyme and causes the enzyme’s shape to change. The shape change activates the enzyme, increasing the rate of glycolysis and the synthesis of ATP. When ATP is in abundance, it binds to the same site on the enzyme as ADP and AMP, but in this case binding inhibits the enzyme’s catalytic activity. As a result, glycolysis and the rate of ATP production slow down.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 7.20 Regulation of PFK-1. The regulation of the glycolytic enzyme phosphofructokinase-1 (PFK-1) is an example of integrated metabolic control.

PFK-1 is also regulated by one of its downstream products, citrate, an intermediate in the citric acid cycle (see [Fig. 7.8](#)). Citrate acts as an allosteric inhibitor of the enzyme, slowing its activity. High levels of citrate indicate that it is not being consumed by the citric acid cycle and glucose breakdown can be slowed. The role of citrate in controlling glycolysis is an example of how the activity of glycolysis and the citric acid cycle is coordinated.

## Exercise requires several types of fuel molecules and the coordination of

## metabolic pathways.

In the last two chapters, we considered what energy is and how it is harnessed by cells. Let's apply the concepts we discussed to a familiar example: exercise. Exercise such as running, walking, and swimming is a form of kinetic energy, powered by ATP in muscle cells. Where does this ATP come from?

Muscle cells, like all cells, do not contain a lot of ATP, and stored ATP is depleted by exercise in a matter of seconds. As a result, muscle cells rely on fuel molecules to generate ATP. For a short sprint or a burst of activity, muscle can convert stored glycogen to glucose, and then break down glucose anaerobically to pyruvate and lactic acid by lactic acid fermentation. This pathway is rapid, but it does not generate a lot of ATP.

For longer, more sustained exercise, other metabolic pathways come into play. Muscle cells contain many mitochondria, which produce ATP by aerobic respiration. The energy yield of aerobic respiration is much greater than that of fermentation, but the process is slower. This slower production of ATP by aerobic respiration in part explains why runners cannot maintain the pace of a sprint for longer runs.

For even longer exercise, liver glycogen supplements muscle glycogen: the liver releases glucose into the blood that is taken up by muscle cells and oxidized to produce ATP. In addition, fatty acids are released from adipose tissue and taken up by muscle cells, where they are broken down by  $\beta$ -oxidation.  $\beta$ -oxidation yields even more ATP than does the complete oxidation of glucose, but the process is again

slower. Storage forms of energy molecules, such as fatty acids and glycogen, contain large reservoirs of energy, but are slow to mobilize. Thus, exercise takes coordination between different cells, tissues, and metabolic pathways to ensure adequate ATP to meet the needs of working muscle.

Self-Assessment Question

15. How does muscle tissue generate ATP during short-term and long-term exercise?

## CORE CONCEPTS SUMMARY

**7.1 AN OVERVIEW OF CELLULAR RESPIRATION:** Cellular respiration is a series of catabolic reactions that converts the energy in fuel molecules into energy in ATP.

During cellular respiration, sugar molecules such as glucose are broken down in the presence of oxygen to produce carbon dioxide and water. [page 135](#)

Cellular respiration releases energy because the potential energy of the reactants is greater than that of the products. [page 136](#)

ATP is generated in two ways during cellular respiration: substrate-level phosphorylation and oxidative phosphorylation. [page 136](#)

Cellular respiration is an oxidation–reduction reaction. [page 136](#)

In oxidation–reduction reactions, electrons are transferred from one molecule to another. Oxidation is the loss of electrons, and reduction is the gain of electrons. [page 136](#)

Electron carriers transfer electrons to an electron transport chain, which harnesses the energy of these electrons to generate ATP. [page 137](#)

Cellular respiration is a four-stage process that includes (1) glycolysis; (2) pyruvate oxidation; (3) the citric acid cycle; and (4) oxidative phosphorylation. [page 137](#)

**7.2 GLYCOLYSIS:** Glycolysis is the partial oxidation of glucose and results in the production of pyruvate, as well as ATP and reduced

electron carriers.

Glycolysis takes place in the cytoplasm. [page 138](#)

Glycolysis is a series of 10 reactions in which glucose is oxidized to pyruvate. [page 139](#)

Glycolysis consists of preparatory, cleavage, and payoff phases. [page 139](#)

For each molecule of glucose broken down during glycolysis, a net gain of two molecules of ATP and two molecules of NADH is produced. [page 139](#)

The synthesis of ATP in glycolysis results from the direct transfer of a phosphate group from a substrate to ADP, a process called substrate-level phosphorylation. [page 139](#)

**7.3 PYRUVATE OXIDATION:** Pyruvate is oxidized to acetyl-CoA, connecting glycolysis to the citric acid cycle.

The conversion of pyruvate to acetyl-CoA results in the production of one molecule of NADH and one molecule of carbon dioxide. [page 141](#)

Pyruvate oxidation occurs in the mitochondrial matrix. [page 141](#)

**7.4 THE CITRIC ACID CYCLE:** The citric acid cycle results in the complete oxidation of fuel molecules and the generation of ATP and reduced electron carriers.

The citric acid cycle takes place in the mitochondrial matrix. [page 142](#)

The acetyl group of acetyl-CoA is completely oxidized in the citric acid cycle. [page 142](#)

The citric acid cycle is a cycle because the acetyl group of acetyl-CoA combines with oxaloacetate, and then a series of reactions regenerates oxaloacetate. [page 143](#)

A complete turn of the citric acid cycle results in the production of one molecule of GTP (which is converted to ATP), three molecules of NADH, and one molecule of FADH<sub>2</sub>. [page 143](#)

Citric acid cycle intermediates are starting points for the synthesis of many different organic molecules. [page 143](#)

**7.5 THE ELECTRON TRANSPORT CHAIN AND OXIDATIVE PHOSPHORYLATION:** The electron transport chain transfers electrons from electron carriers to oxygen, using the energy to pump protons and synthesize ATP by oxidative phosphorylation.

NADH and FADH<sub>2</sub> donate electrons to the electron transport chain. [page 144](#)

In the electron transport chain, electrons move from one redox couple to the next. [page 144](#)

The electron transport chain is made up of four complexes. Complexes I and II accept electrons from NADH and FADH<sub>2</sub>, respectively. The electrons are transferred from these two complexes to coenzyme Q. [page 144](#)

Reduced coenzyme Q transfers electrons to complex III and cytochrome *c* transfers electrons to complex IV. Complex IV

reduces oxygen to water. [page 144](#)

The transfer of electrons through the electron transport chain is coupled with the movement of protons across the inner mitochondrial membrane into the intermembrane space. [page 144](#)

The buildup of protons in the intermembrane space results in a proton electrochemical gradient, which stores potential energy. [page 144](#)

The movement of protons back into the mitochondrial matrix through the  $F_0$  subunit of ATP synthase is coupled with the formation of ATP, a reaction catalyzed by the  $F_1$  subunit of ATP synthase. [page 146](#)

Complete oxidation of one glucose molecule by the four stages of aerobic cellular respiration nets approximately 32 molecules of ATP. [page 146](#)

**7.6 ANAEROBIC METABOLISM:** Glucose can be broken down in the absence of oxygen by fermentation, producing a modest amount of ATP.

Pyruvate, the end product of glycolysis, is processed differently in the presence and the absence of oxygen. [page 148](#)

In the absence of oxygen, pyruvate enters one of several fermentation pathways. [page 148](#)

In lactic acid fermentation, pyruvate is reduced to lactic acid. [page 148](#)

In ethanol fermentation, pyruvate is converted to acetaldehyde, which is reduced to ethanol. [page 148](#)

During fermentation, NADH is oxidized to NAD<sup>+</sup>, allowing glycolysis to proceed. [page 148](#)

Glycolysis and fermentation are ancient biochemical pathways and were likely used in the common ancestor of all organisms living today. [page 149](#)

**7.7 METABOLIC INTEGRATION:** Metabolic pathways are integrated, allowing control of the energy level of cells.

Excess glucose molecules are linked together and stored in polymers called glycogen (in animals) and starch (in plants). [page 150](#)

Other monosaccharides derived from the digestion of dietary carbohydrates are converted into intermediates of glycolysis. [page 151](#)

Fatty acids contained in triacylglycerols are an important form of energy storage in cells. The breakdown of fatty acids is called  $\beta$ -oxidation. [page 151](#)

Phosphofructokinase-1 controls a key step in glycolysis. It has many allosteric activators, including ADP and AMP, and allosteric inhibitors, including ATP and citrate. [page 153](#)

The ATP in muscle cells used to power exercise is generated by lactic acid fermentation, aerobic respiration, and  $\beta$ -oxidation. [page 153](#)

# CHAPTER 8 Photosynthesis

## Using Sunlight to Build Carbohydrates

ooyoo/Getty Images

---

### CORE CONCEPTS

**8.1 AN OVERVIEW OF PHOTOSYNTHESIS:** Photosynthesis is the major pathway by which energy and carbon are incorporated into

carbohydrates.

**8.2 THE CALVIN CYCLE:** The Calvin cycle is a three-step process that uses carbon dioxide to synthesize carbohydrates.

**8.3 CAPTURING SUNLIGHT INTO CHEMICAL FORMS:** The light-harvesting reactions use sunlight to produce the ATP and NADPH required by the Calvin cycle.

**8.4 PHOTOSYNTHETIC CHALLENGES:** Challenges to the efficiency of photosynthesis include excess light energy and the oxygenase activity of rubisco.

**8.5 THE EVOLUTION OF PHOTOSYNTHESIS:** The evolution of photosynthesis had a profound impact on life on Earth.

---

Walk through a forest and you will be struck, literally if you aren't careful, by the substantial nature of trees. Where does the material to construct these massive organisms come from? Because trees grow upward from a firm base in the ground, a reasonable first guess is the soil. In the first recorded experiment on this question, the Flemish chemist and physiologist Jan Baptist van Helmont (1580–1644) found that the 200 pounds of dry soil into which he had planted a small willow tree decreased by only 2 ounces over a 5-year period. During this same period, the tree gained 164 pounds. Van Helmont concluded that water must be responsible for the tree's growth. He was, in fact, half right: a tree is roughly half liquid water. However, what he missed completely is that the other half of his tree had been created almost entirely out of thin air.

The process that allowed Van Helmont's tree to increase in mass

using material pulled from the air is called [\*\*photosynthesis\*\*](#).

Photosynthesis is a biochemical process for building carbohydrates using energy from sunlight and carbon dioxide ( $\text{CO}_2$ ) taken from the air. These carbohydrates are used both as starting points for the synthesis of other molecules and as a means of storing energy in chemical bonds. As we saw in [Chapter 7](#), plants and animals alike need energy in the form of ATP to power the work of the cell. The energy from sunlight is converted into the energy in the chemical bonds of carbohydrates, and that energy, in turn, can be converted into ATP through cellular respiration.

## 8.1 AN OVERVIEW OF PHOTOSYNTHESIS

Photosynthesis is the major entry point for energy into biological systems. It is the source of all of the food we eat, both directly when we consume plant material and indirectly when we consume meat. It is also the source of all the oxygen that we breathe, as well as the fuels we use for heating and transportation. Fossil fuels are the legacy of ancient photosynthesis: oil has its origin in the bodies of marine algae and the organisms that grazed on them, whereas coal represents the geologic remains of terrestrial (land) plants. Thus, one motivation to understand photosynthesis is the sheer magnitude and importance of this process for life on Earth. Before exploring the details of how photosynthesis actually occurs, let's look at what types of organism carry out photosynthesis and where they live, as well as what structural components allow cells to capture energy in this remarkable way.

### Photosynthesis is widely distributed.

The photosynthesis that is most evident to us is carried out by plants on land. Trees, grasses, and shrubs are all examples of photosynthetic organisms. However, photosynthesis is carried out by prokaryotic as well as eukaryotic organisms, on land as well as in the sea.

Approximately 60% of global photosynthesis is carried out by terrestrial organisms, with the remaining 40% taking place in the ocean. The majority of photosynthetic organisms in marine environments are unicellular. About half of oceanic photosynthesis is carried out by single-celled marine eukaryotes, while the other half is carried out by photosynthetic bacteria.

Photosynthesis takes place almost everywhere sunlight is available to serve as a source of energy. In the ocean, photosynthesis occurs in the surface layer extending to about 100 m deep, called the [photic zone](#), through which enough sunlight penetrates to enable photosynthesis. On land, photosynthesis occurs most readily in environments that are both moist and warm. Tropical rain forests have high photosynthetic productivity, as do grasslands and forests in the temperate zone. However, photosynthetic organisms have evolved adaptations that allow them to tolerate a wide range of environmental conditions, like those illustrated in [Fig. 8.1](#). In very dry regions, a combination of photosynthetic bacteria and unicellular algae forms an easily disturbed layer on the surface of the soil known as desert crust. Photosynthetic bacteria are also found in the hot springs of Yellowstone National Park at temperatures up to 75°C. At the other extreme, unicellular algae can grow on the surfaces of glaciers, causing the snow to appear red. In [section 8.4](#), we discuss why photosynthetic organisms growing in such extreme environments often appear red or yellow rather than green.

FIG. 8.1 Photosynthesis in extreme environments. (a) Desert crust in the Colorado Plateau formed by photosynthetic bacteria and algae. (b) A hot spring in Yellowstone National Park. The yellow color is due to photosynthetic bacteria. (c) The surface of a permanent snow pack. The red color is due to photosynthetic algae.

## Photosynthesis is a redox reaction.

Carbohydrates are synthesized from  $\text{CO}_2$  molecules during

photosynthesis, yet they have more energy stored in their chemical bonds than is contained in the bonds of  $\text{CO}_2$  molecules. Therefore, to build carbohydrates using  $\text{CO}_2$  requires an input of energy. This energy comes from sunlight.

How does energy from sunlight become incorporated into chemical bonds? The answer to this question arises from the fact that the synthesis of carbohydrates from  $\text{CO}_2$  and water is a reduction–oxidation, or redox, reaction. In [Chapter 7](#), we saw that **reduction** reactions are reactions in which a molecule acquires electrons and gains energy, whereas **oxidation** reactions are reactions in which a molecule loses electrons and releases energy. During photosynthesis,  $\text{CO}_2$  molecules are reduced to form higher-energy carbohydrate molecules ([Fig. 8.2](#)).

FIG. 8.2 Overview of photosynthesis. In photosynthesis, energy from sunlight is used to synthesize carbohydrates from  $\text{CO}_2$ .

Where do the electrons used to reduce  $\text{CO}_2$  come from? In photosynthesis carried out by plants and many algae, the ultimate electron donor is water. The oxidation of water results in the production of electrons, protons, and  $\text{O}_2$ . Thus, oxygen is formed in photosynthesis as a by-product of water's role as a source of electrons. We can demonstrate that water is the source of the oxygen released during photosynthesis using isotopes, which are elements that have different numbers of neutrons and thus can be distinguished on the

basis of their mass ([Fig. 8.3](#)).

#### HOW DO WE KNOW?

### FIG. 8.3

## Does the oxygen released by photosynthesis come from $\text{H}_2\text{O}$ or $\text{CO}_2$ ?

#### BACKGROUND

The reactants in photosynthesis are water and carbon dioxide. Both contain oxygen, so it is unclear which one is the source of the oxygen gas that is produced in the reaction. How did scientists determine whether the source of oxygen is water or carbon dioxide?

#### METHOD

Isotopes were used to identify the source of oxygen in photosynthesis. Most of the oxygen in the atmosphere is  $^{16}\text{O}$ , a stable isotope containing 8 protons and 8 neutrons. A small amount (0.2%) is  $^{18}\text{O}$ , a stable isotope with 8 protons and 10 neutrons. The relative abundance of molecules containing  $^{16}\text{O}$  versus  $^{18}\text{O}$  can be measured using a mass spectrometer. Water and carbon dioxide containing a high percentage of  $^{18}\text{O}$  were prepared, and separate solutions of the algae *Chlorella* were exposed to each one.

#### EXPERIMENT

## RESULTS

## CONCLUSION

The percentage of  $^{18}\text{O}_2$  produced by photosynthesis in the algae increased only when water contained a high percentage of  $^{18}\text{O}$ , but not when carbon dioxide contained a high percentage of  $^{18}\text{O}$ . This finding indicates that the oxygen produced in photosynthesis comes from water, not carbon dioxide.

## FOLLOW-UP WORK

Carbon also has several isotopes. The measurement of the relative abundance of these isotopes has been used to determine the source of increased carbon dioxide in the atmosphere today (Chapter 46).

SOURCE Adapted from Ruben, S., M. Randall, M. Kamen, and J. L. Hyde. 1941. "Heavy Oxygen ( $\text{O}^{18}$ ) as a Tracer in the Study of Photosynthesis." *Journal of the American*

Overall, then, the equation for photosynthesis leading to the synthesis of glucose ( $\text{C}_6\text{H}_{12}\text{O}_6$ ) can be described as follows:

The oxidation of water is linked with the reduction of  $\text{CO}_2$  through a series of redox reactions in which electrons are passed from one compound to another. This series of reactions constitutes the **photosynthetic electron transport chain**. The process begins with the absorption of sunlight by protein–pigment complexes. The absorbed sunlight provides the energy that drives electrons through the photosynthetic electron transport chain. In turn, the movement of electrons through this transport chain is used to produce ATP and the electron carrier **nicotinamide adenine dinucleotide phosphate (NADPH)**. Finally, ATP and NADPH are the energy sources needed to synthesize carbohydrates using  $\text{CO}_2$  in a process called the **Calvin cycle** (see Fig. 8.2). In eukaryotes, all of these processes, both the capture of light energy and the synthesis of carbohydrates, take place in chloroplasts.

Although photosynthetic organisms are correctly described as

autotrophs because they can form carbohydrates from  $\text{CO}_2$ , they also require a constant supply of ATP to meet each cell's energy requirements. ATP is produced within chloroplasts, but only carbohydrates (and not ATP) are exported from chloroplasts to the cytosol. This explains why cells that have chloroplasts also contain mitochondria. In mitochondria, carbohydrates are broken down to generate ATP ([Chapter 7](#)). Cellular respiration is therefore one of several features that heterotrophic organisms like ourselves share with photosynthetic organisms.

## The photosynthetic electron transport chain takes place in specialized membranes.

Electron transport chains play a key role in both photosynthesis and respiration ([Chapter 7](#)). In both cases, electrons move within and between large protein complexes embedded in specialized membranes. In photosynthetic bacteria, the photosynthetic electron transport chain is located in membranes within the cytoplasm or, in some cases, directly in the plasma membrane. In eukaryotic cells, photosynthesis takes place in chloroplasts. In the center of the chloroplast is the highly folded **thylakoid membrane** ([Fig. 8.4](#)). The photosynthetic electron transport chain is located in the thylakoid membrane.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Source: Biophoto Associates/Science Source.

FIG. 8.4 Chloroplast structure. Chloroplasts contain highly folded thylakoid membranes.

The name “thylakoid” is derived from *thylakois*, the Greek word for “sac.” Thylakoid membranes form structures that resemble flattened sacs, and these sacs are grouped into structures called **grana** (singular, granum) that look like stacks of interlinked pancakes. Grana are connected to one another by membrane bridges in such a way that the thylakoid membrane encloses a single interconnected compartment called the **lumen**. The region surrounding the thylakoid membrane is called the **stroma**. Carbohydrate synthesis takes place in the **stroma**, whereas sunlight is captured and transformed into chemical energy by the photosynthetic electron transport chain in the thylakoid membrane.

Next, we consider the underlying biochemistry of photosynthesis. In this chapter, we focus on photosynthesis as carried out by eukaryotic cells, but remarkable diversity exists in the way it is carried out in bacteria. We discuss this diversity in Chapter 24. Because carbohydrates are the major product of photosynthesis, we first examine the Calvin cycle, the biochemical pathway used in photosynthesis to synthesize carbohydrates from  $\text{CO}_2$ . Once we understand what energy forms are needed to drive this autotrophic pathway, we turn our attention to how energy is captured from sunlight. We then examine some of the challenges of coordinating these two metabolic stages and consider ways in which photosynthetic organisms cope with the inherent biochemical challenges of photosynthesis. Finally, we provide a short overview of the evolutionary history of photosynthesis.

#### Self-Assessment Questions

1. Write the overall reaction for photosynthesis. Which molecules are oxidized and which molecules are reduced?
2. If you want to produce carbohydrates that contain the heavy oxygen ( $^{18}\text{O}$ ) isotope, should you water your plants with  $\text{H}_2^{18}\text{O}$  or inject  $\text{C}^{18}\text{O}_2$  into the air?
3. How are the overall reactions for photosynthesis and cellular respiration similar and how are they different?

## 8.2 THE CALVIN CYCLE

The Calvin cycle consists of 15 chemical reactions that synthesize carbohydrates from  $\text{CO}_2$ . These reactions can be grouped into three main steps: (1) **carboxylation**, in which  $\text{CO}_2$  is added to a 5-carbon molecule; (2) **reduction**, in which energy and electrons are transferred to the compounds formed in step 1; and (3) **regeneration** of the 5-carbon molecule needed for carboxylation (**Fig. 8.5**). Carbon and oxygen make up more than 90% of the mass of a carbohydrate molecule, such that step 1 represents the major input of raw materials. The major input of energy occurs in step 2. Without this input of energy from ATP and NADPH, carbohydrates could not be produced from  $\text{CO}_2$ . Step 3 is essential because without the 5-carbon molecule needed for carboxylation, the Calvin cycle cannot proceed.

FIG. 8.5 The Calvin cycle.  $\text{CO}_2$  is the input and triose phosphate is the output of the Calvin cycle.

---

## The incorporation of $\text{CO}_2$ is catalyzed by the enzyme rubisco.

In the first step of the Calvin cycle ([Fig. 8.5](#)),  $\text{CO}_2$  is added to a 5-carbon sugar called [ribulose 1,5-bisphosphate \(RuBP\)](#). This step is catalyzed by the enzyme [ribulose bisphosphate carboxylase oxygenase](#), or **rubisco** for short. An enzyme that adds  $\text{CO}_2$  to another molecule is called a carboxylase, explaining part of rubisco's long name.

Before rubisco can act as a carboxylase, RuBP and  $\text{CO}_2$  must diffuse into its active site. Once the active site is occupied, the addition of  $\text{CO}_2$  to RuBP proceeds spontaneously in the sense that no addition of energy is required. The product is a 6-carbon compound that immediately breaks into two molecules of [3-phosphoglycerate \(3-PGA\)](#). These 3-carbon molecules are the first stable products of the Calvin cycle.

## NADPH is the reducing agent of the Calvin cycle.

Rubisco is responsible for the addition of the carbon atoms needed for the formation of carbohydrates, but rubisco alone does not increase the amount of energy stored within the newly formed bonds. For this energy increase to take place, the carbon compounds formed by rubisco must be reduced. NADPH is the reducing agent used in the Calvin cycle. NADPH transfers the electrons that allow carbohydrates to be synthesized from  $\text{CO}_2$  ([Fig. 8.5](#)).

In the Calvin cycle, the reduction of 3-PGA involves two reactions: (1) ATP donates a phosphate group to 3-PGA, and (2) NADPH transfers two electrons plus one proton ( $H^+$ ) to the phosphorylated compound, which releases one phosphate group ( $P_i$ ). Because two molecules of 3-PGA are formed each time rubisco catalyzes the incorporation of one molecule of  $CO_2$ , two ATP and two NADPH are required for each molecule of  $CO_2$  incorporated by rubisco. NADPH provides most of the energy incorporated in the bonds of the carbohydrate molecules produced by the Calvin cycle. Nevertheless, ATP plays an essential role in preparing 3-PGA for the addition of energy and electrons from NADPH.

These energy transfer steps result in the formation of 3-carbon carbohydrate molecules known as **triose phosphates**. Triose phosphates are the true products of the Calvin cycle and the principal form of carbohydrate exported from the chloroplast during photosynthesis. However, if every triose phosphate molecule produced by the Calvin cycle were exported from the chloroplast, RuBP could not be regenerated and the Calvin cycle would grind to a halt. In fact, most of the triose phosphate molecules must be used to regenerate RuBP. For every six triose phosphate molecules produced, only one can be withdrawn from the Calvin cycle.

## The regeneration of RuBP requires ATP.

Of the 15 chemical reactions that make up the Calvin cycle, 12 occur in the last step, the regeneration of RuBP ([Fig. 8.5](#)). Many reactions are needed to rearrange the carbon atoms from five 3-carbon triose

phosphate molecules into three 5-carbon RuBP molecules. ATP is required for the regeneration of RuBP, raising the Calvin cycle's total energy requirements to two molecules of NADPH and three molecules of ATP for each molecule of  $\text{CO}_2$  incorporated by rubisco.

The Calvin cycle does not use sunlight directly. For this reason, this pathway is sometimes referred to as the light-independent or even the “dark” reactions of photosynthesis. However, this pathway cannot operate without the energy input provided by a steady supply of NADPH and ATP. Both are supplied by the photosynthetic electron transport chain, in which light is captured and transformed into chemical energy. In addition, several Calvin cycle enzymes are regulated by cofactors that must be activated by the photosynthetic electron transport chain. Thus, in a photosynthetic cell, the Calvin cycle occurs only in the light.

## The steps of the Calvin cycle were determined using radioactive $\text{CO}_2$ .

In a series of experiments conducted between 1948 and 1954, the American chemist Melvin Calvin and colleagues identified the carbon compounds produced during photosynthesis ([Fig. 8.6](#)). They supplied radioactively labeled  $\text{CO}_2$  ( $^{14}\text{CO}_2$ ) to the unicellular green alga *Chlorella*, and then plunged the cells into boiling alcohol, thereby halting all enzymatic reactions. The carbon compounds produced during photosynthesis were thus radioactively labeled and could be identified by their radioactivity (Experiment 1 in [Fig. 8.6](#)).

HOW DO WE KNOW?

## FIG. 8.6

### How is $\text{CO}_2$ incorporated into carbohydrates?

#### BACKGROUND

In the 1940s, radioactive  $^{14}\text{CO}_2$  became available in quantities that allowed scientists to use it for experiments. Melvin Calvin and Andrew Benson used  $^{14}\text{CO}_2$  to follow the incorporation of  $\text{CO}_2$  into carbohydrates.

#### EXPERIMENTS AND RESULTS

#### CONCLUSION

Preventing carboxylation resulted in an excess of RuBP and less 3-PGA, leading researchers to determine that the initial step in the Calvin cycle unites the 5-carbon RuBP with  $\text{CO}_2$ , resulting in the production of two molecules of 3-PGA.

#### FOLLOW-UP WORK

In the 1950s, Marshall Hatch and colleagues showed that some plants,

including corn and sugarcane, accumulate a 4-carbon compound as the first product in photosynthesis. In Chapter 27, we explore how  $C_4$  photosynthesis allows plants to avoid the reaction of rubisco with oxygen.

SOURCE Calvin, M., and H. Benson. 1949. "The Path of Carbon in Photosynthesis IV: The Identity and Sequence of the Intermediates in Sucrose Synthesis." *Science* 109:140–142.

Additional experiments were required, however, to determine the chemical reactions that connected these labeled compounds. For example, by using a very short exposure to  $^{14}CO_2$ , Calvin and colleagues determined that 3-PGA was the first stable product of the Calvin cycle (Experiment 2 in [Fig. 8.6](#)).

To determine how 3-PGA is formed, they first supplied  $^{14}CO_2$  so that all of the molecules in the Calvin cycle became radioactively labeled. When they then cut off the supply of  $CO_2$ , the amount of RuBP increased relative to the amount observed in the first experiment. Based on this buildup of RuBP, they concluded that the first step in the Calvin cycle was the addition of  $CO_2$  to RuBP (Experiment 3 in [Fig. 8.6](#)).

## Carbohydrates are stored in the form of starch.

The Calvin cycle is capable of producing more carbohydrates than the cell needs or, in a multicellular organism, more than the cell is able to export. If carbohydrates accumulated in the cell, they would cause water to enter the cell by osmosis, perhaps damaging the cell. Instead, excess carbohydrates are converted to starch, a storage form of

carbohydrates discussed in [Chapter 2](#). Because starch molecules are not soluble, they provide a means of carbohydrate storage that does not lead to osmosis. Starch formed during the day provides photosynthetic cells with a source of carbohydrates that they can use during the night ([Fig. 8.7](#)).

FIG. 8.7 A chloroplast containing starch granules, shown here in yellow.

#### Self-Assessment Questions

4. What are the major inputs and outputs of the Calvin cycle?

5. What are the three major steps in the Calvin cycle and the role of the enzyme rubisco?
6. The Calvin cycle requires both ATP and NADPH. Which of these molecules provides the major input of energy needed to synthesize carbohydrates?

## 8.3 CAPTURING SUNLIGHT INTO CHEMICAL FORMS

In order for sunlight to power the Calvin cycle, the cell must be able to use light energy to produce both NADPH and ATP. In photosynthesis, light energy absorbed by pigment molecules drives the flow of electrons through the photosynthetic electron transport chain, and this flow of electrons leads to the formation of both NADPH and ATP.

### Chlorophyll is the major entry point for light energy in photosynthesis.

To understand how energy from sunlight is captured and stored by photosynthesis, we need to know a little about light. The sun, like all stars, produces a broad spectrum of electromagnetic radiation, ranging from gamma rays to radio waves. Each point along the electromagnetic spectrum has a different energy level and a corresponding wavelength. Visible light is the portion of the electromagnetic spectrum apparent to our eyes, and it includes the range of wavelengths used in photosynthesis. The wavelengths of visible light range from 400 nm to 700 nm. Approximately 40% of the sun's energy that reaches Earth's surface is in this range.

Pigments are molecules that absorb some wavelengths of visible light. Pigments look colored because they reflect light enriched in the wavelengths that they do not absorb. Chlorophyll is the major photosynthetic pigment. The graph in Fig. 8.8 shows the extent to which wavelengths of visible light are absorbed by pigments in an intact leaf. Leaves appear green because they are poor at absorbing

green wavelengths.

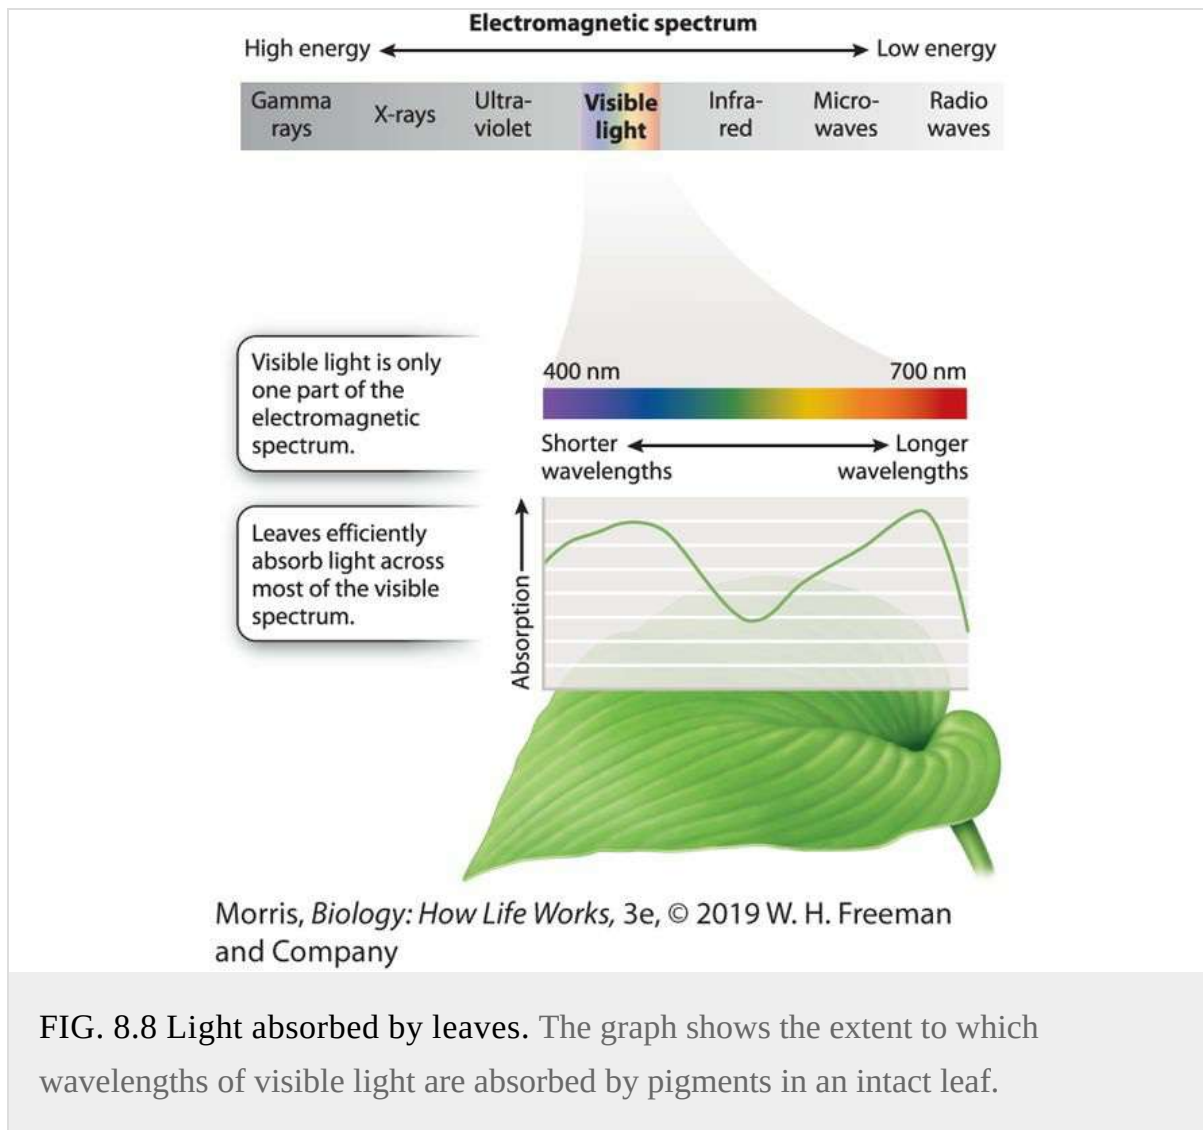

FIG. 8.8 Light absorbed by leaves. The graph shows the extent to which wavelengths of visible light are absorbed by pigments in an intact leaf.

The chlorophyll molecule consists of a large, light-absorbing “head” that contains a magnesium atom at its center and a long hydrocarbon “tail” ([Fig. 8.9](#)). The large number of alternating single and double bonds in the head region explains why chlorophyll is so efficient at absorbing visible light. Chlorophyll molecules are bound to integral membrane proteins in the thylakoid membrane. These protein–pigment complexes, referred to as [photosystems](#), are the functional and structural units that absorb light energy and use it to drive electron

transport.

Photosystems contain pigments other than chlorophyll, called [accessory pigments](#). The most notable are the orange-yellow carotenoids, which can absorb light from regions of the visible

spectrum that are poorly absorbed by chlorophyll. Thus, the presence of these accessory pigments allows photosynthetic cells to absorb a broader range of visible light than would be possible with just chlorophyll alone. As we will see in [section 8.4](#), carotenoids play an important role in protecting the photosynthetic electron transport chain from damage.

## Antenna chlorophyll passes light energy to reaction centers.

When a chlorophyll molecule absorbs visible light, one of its electrons is elevated to a higher energy state ([Fig. 8.10](#)). For chlorophyll molecules that have been extracted from chloroplasts in the laboratory, this absorbed light energy is rapidly released, allowing the electron to return to its initial “ground” energy state ([Fig. 8.10a](#)). Most of the energy (more than 95%) is converted into heat; a small amount is reemitted as light (fluorescence).

FIG. 8.10 Absorption of light energy by chlorophyll. Absorption of light energy by (a) an isolated chlorophyll molecule in the lab and (b) an antenna chlorophyll molecule.

By contrast, chlorophyll molecules within an intact chloroplast can transfer energy to an adjacent chlorophyll molecule instead of losing the energy as heat ([Fig. 8.10b](#)). Energy is still released as an excited electron returns to its ground state, but the release of this energy raises the energy level of an electron in an adjacent chlorophyll molecule. This mode of energy transfer is extremely efficient (that is, very little energy is lost as heat), allowing energy initially absorbed from sunlight to be transferred from one chlorophyll molecule to another and then on to another.

Most of the chlorophyll molecules in the thylakoid membrane function as an antenna: energy is transferred between chlorophyll molecules until it is finally transferred to a specially configured pair of chlorophyll molecules known as the [reaction center](#) ([Fig. 8.11](#)).

FIG. 8.11 The reaction center. (a) Antenna chlorophylls deliver absorbed light energy to the reaction center, allowing an electron to be transferred to an electron acceptor. (b) After the reaction center has lost an electron, it must gain an electron from an electron donor before it can absorb additional light energy.

The reaction center is where light energy is converted into chemical energy: the excited electron itself, not just its energy, is transferred to an adjacent molecule. This division of labor among chlorophyll molecules was discovered in the 1940s in a series of experiments by the American biophysicists Robert Emerson and William Arnold, who showed that only a small fraction of chlorophyll molecules are directly involved in electron transport ([Fig. 8.12](#)). We now know that several hundred antenna chlorophyll molecules transfer energy to each reaction center. The antenna chlorophylls allow the photosynthetic electron transport chain to operate efficiently. Without the antennae to gather light energy, reaction centers would sit idle much of the time, even in bright sunlight.

#### HOW DO WE KNOW?

### FIG. 8.12

## Do chlorophyll molecules operate on their own or in groups?

#### BACKGROUND

By about 1915, scientists knew that chlorophyll was the pigment responsible for absorbing light energy in photosynthesis. However, it was unclear how these pigments contributed to the reduction of  $\text{CO}_2$ . The American physiologists Robert Emerson and William Arnold set out to determine the nature of the “photochemical unit” by quantifying how

many chlorophyll molecules are needed to produce one molecule of  $\text{O}_2$ .

### EXPERIMENT

Emerson and Arnold exposed flasks of the green alga *Chlorella* to flashes of light of very short duration ( $10^{-5}$  s) and high intensity (several times more intense than full sunlight) in order to “excite” each chlorophyll molecule just one time. They also made sure that the time between flashes was long enough to allow the reactions resulting from each flash to run to completion. They then determined the number of  $\text{O}_2$  molecules produced per flash of high-intensity light and measured the concentration of chlorophyll present in their solution of cells.

### RESULTS

### CONCLUSION

Because the number of chlorophyll molecules in their flasks was much greater than the number of  $\text{O}_2$  molecules produced per flash, Emerson and Arnold concluded that many chlorophyll molecules are needed to produce one  $\text{O}_2$  molecule and that each photochemical unit must contain many chlorophyll molecules.

### FOLLOW-UP WORK

Emerson and Arnold's work was followed by studies that demonstrated that the photosynthetic electron transport chain contains two photosystems arranged in series.

SOURCE Emerson, R., and W. Arnold. 1932. "The Photochemical Reaction in Photosynthesis." *Journal of General Physiology* 16:191–205.

The reaction center chlorophylls have a configuration distinct from that of the antenna chlorophylls. Therefore, when excited, the reaction center transfers an electron to an adjacent molecule that acts as an electron acceptor ([Fig. 8.11a](#)). When the transfer takes place, the reaction center becomes oxidized and the adjacent electron-acceptor molecule is reduced. The result is the conversion of light energy into a chemical form. This electron transfer initiates a light-driven chain of redox reactions that leads ultimately to the formation of NADPH.

Once the reaction center has lost an electron, it can no longer absorb light or contribute additional electrons. Thus, for the photosynthetic electron transport chain to continue, another electron must be delivered to take the place of the one that has entered the transport chain ([Fig. 8.11b](#)). As we will see below, these replacement electrons ultimately come from water.

## The photosynthetic electron transport chain connects two photosystems.

In many ways, water is an ideal source of electrons for photosynthesis. Water is so abundant within cells that it is always available to serve as an electron donor. In addition,  $O_2$ , the by-product of pulling electrons

from water, diffuses readily away. From an energy perspective, however, water is a challenging electron donor: it takes a great deal of energy to pull electrons from water. The amount of energy that a single photosystem can capture from sunlight is not enough to simultaneously pull an electron from water and produce an electron donor capable of reducing  $\text{NADP}^+$  to NADPH. The solution is to use two photosystems, each with distinct chemical properties, arranged in series ([Fig. 8.13](#)). The energy supplied by the first photosystem allows electrons to be pulled from water, and the energy supplied by the second photosystem allows electrons to be transferred to  $\text{NADP}^+$  to form NADPH.

FIG. 8.13 The Z scheme. The use of water as an electron donor requires input of light energy at two places in the photosynthetic electron transport chain.

If you follow the flow of electrons from water through both

photosystems and on to  $\text{NADP}^+$ , as shown in [Fig. 8.13](#), you can see a large increase in energy as the electrons pass through each of the two photosystems. You can also see that an overall decrease in energy occurs as electrons move between the two photosystems. This decrease in energy explains why electrons move in one “direction” through the photosynthetic electron transport chain. To run these reactions in the opposite direction would require an input of energy. Because the overall energy trajectory has an up-down-up configuration resembling a “Z,” the photosynthetic electron transport chain is sometimes referred to as the [Z scheme](#).

The major protein complexes of the photosynthetic electron transport chain include the two photosystems as well as the [cytochrome- \$b\_6f\$  complex \(Cyt\)](#) in between ([Fig. 8.14](#)). Small, relatively mobile compounds convey electrons between these protein complexes: plastoquinone (Pq) diffuses through the membrane from photosystem II (PSII) to the cytochrome- $b_6f$  complex, and plastocyanin (Pc) diffuses through the thylakoid lumen from the cytochrome- $b_6f$  complex to photosystem I (PSI).

FIG. 8.14 The photosynthetic electron transport chain. (a) An overview of the production of NADPH and ATP. (b) The linear flow of electrons from  $\text{H}_2\text{O}$  to NADPH. (c) The use of a proton electrochemical gradient to synthesize ATP.

Water donates electrons to one end of the photosynthetic electron

transport chain, whereas  $\text{NADP}^+$  accepts electrons at the other end. The enzyme that pulls electrons from water, releasing both  $\text{H}^+$  and  $\text{O}_2$ , is located on the lumen side of photosystem II. NADPH is formed when electrons are passed from photosystem I to a membrane-associated protein called ferredoxin (Fd) on the stromal side of the thylakoid membrane ([Fig. 8.14b](#)). The enzyme ferredoxin– $\text{NADP}^+$  reductase then catalyzes the formation of NADPH by transferring two electrons from two molecules of reduced ferredoxin to  $\text{NADP}^+$  as well as a proton from the surrounding solution:

## The accumulation of protons in the thylakoid lumen drives the synthesis of ATP.

So far, we have considered only how the photosynthetic electron transport chain leads to the formation of NADPH. However, we know that the Calvin cycle also requires ATP. In chloroplasts, as in mitochondria, ATP is synthesized by ATP synthase, a transmembrane protein powered by a proton gradient ([Chapter 7](#)). In chloroplasts, ATP synthase is oriented such that the synthesis of ATP is the result of the movement of protons from the thylakoid lumen to the stroma, as shown in [Fig. 8.14c](#).

How do protons accumulate in the thylakoid lumen? Two features of the photosynthetic electron transport chain are responsible for the buildup of protons in the thylakoid lumen ([Fig. 8.14c](#)). First, the oxidation of water releases protons and  $\text{O}_2$  into the lumen. Second, the

cytochrome- $b_6f$  complex and plastoquinone together act as a proton pump that functions much like proton pumping in the electron transport chain of cellular respiration ([Chapter 7](#)). In fact, the two proton pumping systems are evolutionarily related.

Together, these mechanisms are quite powerful. When the photosynthetic electron transport chain is operating at full capacity, the concentration of protons in the lumen can be more than 1000 times greater than their concentration in the stroma (equivalent to a difference of 3 pH units). This accumulation of protons on one side of the thylakoid membrane can then be used to power the synthesis of ATP by oxidative phosphorylation as described in [Chapter 7](#).

## Cyclic electron transport increases the production of ATP.

The Calvin cycle requires two molecules of NADPH and three molecules of ATP for each  $\text{CO}_2$  incorporated into carbohydrates. However, the transport of four electrons through the photosynthetic electron transport chain, which is needed to reduce two  $\text{NADP}^+$  molecules, does not transport enough protons into the lumen to produce the required three ATPs. An additional pathway for electrons is needed to increase the production of ATP.

In [cyclic electron transport](#), electrons from photosystem I are redirected from ferredoxin back into the electron transport chain ([Fig. 8.15](#)). These electrons reenter the photosynthetic electron transport chain by plastoquinone. Because these electrons eventually return to photosystem I, this alternative pathway is cyclic in contrast to the

linear movement of electrons from water to NADPH.

How does cyclic electron transport lead to the production of ATP? As the electrons from ferredoxin are picked up by plastoquinone, additional protons are transported from the stroma to the lumen. As a result, there are more protons in the lumen that can be used to drive the synthesis of ATP.

#### Self-Assessment Questions

7. How do antenna chlorophylls differ from reaction center chlorophylls?
8. Why are two photosystems needed when H<sub>2</sub>O is used as an electron donor?

9. How is energy from sunlight used to produce ATP?
10. What are the products of linear electron transport and cyclic electron transport? What is the role of cyclic electron transport?

## 8.4 PHOTOSYNTHETIC CHALLENGES

Two major challenges can hinder photosynthesis from functioning efficiently. The first is that if more light energy is absorbed than the Calvin cycle can use, excess energy can damage the cell. The second challenge stems from a property of rubisco: this enzyme can catalyze the addition of *either* carbon dioxide *or* oxygen to RuBP. The addition of oxygen instead of carbon dioxide can substantially reduce the amount of carbohydrate produced.

### Excess light energy can cause damage.

Photosynthesis is an inherently dangerous enterprise. Unless the photosynthetic reactions are carefully controlled, molecules will form that can damage cells by oxidizing lipids, proteins, and nucleic acids indiscriminately ([Fig. 8.16](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

**FIG. 8.16 Defenses against reactive oxygen species.** (a) Reactive oxygen species are generated when light energy or electrons are transferred to oxygen. (b) Defenses against reactive oxygen species include antioxidants that neutralize these highly reactive molecules.

Under normal conditions, the photosynthetic electron transport chain proceeds in an orderly fashion from the absorption of light to the formation of  $\text{NADPH}$ . When  $\text{NADP}^+$  is in short supply, however, the electron transport chain “backs up” and leaves electrons and energy with no “safe” place to go. This greatly increases the probability of

creating reactive forms of oxygen known collectively as **reactive oxygen species** (Fig. 8.16a). These highly reactive molecules can be formed either by the transfer of absorbed light energy from antenna chlorophyll directly to  $O_2$  or by the transfer of an electron, forming  $O_2^-$ . Both forms of  $O_2$  can cause substantial damage to the cell.

$NADP^+$  is returned to the photosynthetic electron transport chain by the Calvin cycle's use of NADPH. Thus, any factor that causes the rate of NADPH use to fall behind the rate of light-driven electron transport can potentially lead to damage. Such an imbalance is likely to occur, for example, in the middle of the day when light intensity is highest. Could the cell right the balance by supplying  $NADP^+$  more quickly? Photosynthetic cells could speed up the resupply of  $NADP^+$  by synthesizing more Calvin cycle enzymes. This strategy, however, would be energetically expensive. When light levels are low, such as in the morning and late afternoon, Calvin cycle enzymes would sit idle. An alternative strategy of reducing the amount of chlorophyll in the leaf runs into similar problems. Thus, excess light energy is an everyday event for photosynthetic cells, rather than something that occurs only in extreme environments.

The rate at which the Calvin cycle can make use of NADPH is also influenced by a number of factors that are independent of light intensity. For example, at cold temperatures, the enzymes of the Calvin cycle function more slowly, but temperature has little impact on the absorption of light energy. On a cold, sunny day, more light energy is absorbed than can be used by the Calvin cycle.

Photosynthetic organisms employ two major lines of defense to avoid the stresses that occur when the Calvin cycle cannot keep up with light harvesting ([Fig. 8.16b](#)). First among these are chemicals that detoxify reactive oxygen species. Ascorbate (vitamin C),  $\beta$ -(beta-)carotene, and other antioxidants are able to neutralize reactive oxygen species. These compounds exist in high concentration in chloroplasts. Some of these antioxidant molecules are brightly colored, like the red pigments found in algae that live on snow shown in [Fig. 8.1c](#). The presence of antioxidant compounds is one of the many reasons why eating green, leafy vegetables is good for your health.

A second line of defense is to prevent reactive oxygen species from forming in the first place. [Xanthophylls](#) are yellow-orange pigments that slow the formation of reactive oxygen species by reducing excess light energy. These pigments accept absorbed light energy directly from chlorophyll, and then convert this energy to heat ([Fig. 8.16b](#)). Photosynthetic organisms that live in extreme environments often appear brown or yellow because they contain high levels of xanthophyll pigments, as seen in [Figs. 8.1a](#) and [8.1b](#). Plants that lack xanthophylls grow poorly when exposed to moderate light levels and die in full sunlight.

Converting absorbed light energy into heat is beneficial at high light levels, but at low light levels it would decrease the production of carbohydrates. Therefore, this capability is switched on only when the photosynthetic electron transport chain is working at high capacity.

## Photorespiration leads to a net loss of

## energy and carbon.

A second challenge to photosynthetic efficiency is rubisco's ability to use both  $\text{CO}_2$  and  $\text{O}_2$  as substrates. If  $\text{O}_2$  instead of  $\text{CO}_2$  diffuses into the active site of rubisco, the reaction can still proceed, although  $\text{O}_2$  is added to RuBP in place of  $\text{CO}_2$ . An enzyme that adds  $\text{O}_2$  to another molecule is called an oxygenase. Recall that rubisco is shorthand for RuBP carboxylase oxygenase, reflecting rubisco's ability to catalyze two different reactions.

When rubisco adds  $\text{O}_2$  instead of  $\text{CO}_2$  to RuBP, the result is one molecule with three carbon atoms (3-PGA) and one molecule with only two carbon atoms (2-phosphoglycolate). A serious problem is that 2-phosphoglycolate cannot be used by the Calvin cycle to either produce triose phosphate or regenerate RuBP.

A metabolic pathway to recycle 2-phosphoglycolate is present in photosynthetic cells. Some of the carbon atoms in 2-phosphoglycolate are converted into 3-PGA, which can reenter the Calvin cycle. However, other carbon atoms in 2-phosphoglycolate are released as  $\text{CO}_2$ . Because the overall effect is the consumption of  $\text{O}_2$  and release of  $\text{CO}_2$  in the presence of light, this process is referred to as **photorespiration** ([Fig. 8.17](#)). However, whereas respiration produces ATP, photorespiration consumes ATP. In photorespiration, ATP drives the reactions that recycle 2-phosphoglycolate into 3-PGA. Thus, photorespiration represents a net energy drain in two ways: first, it results in the oxidation and loss, in the form of  $\text{CO}_2$ , of carbon atoms that had already been incorporated and reduced by the Calvin cycle; second, it consumes ATP.

FIG. 8.17 Photorespiration. Carbon and energy are lost when rubisco acts as an oxygenase in photosynthesis.

The Calvin cycle originated long before the accumulation of oxygen in Earth's atmosphere, which provides an explanation why an enzyme with these properties might have initially evolved. Still, why would photorespiration persist in the face of what must be strong evolutionary pressure to reduce or eliminate the unwanted reaction with oxygen?

The difficulty is that in order for rubisco to favor the addition of CO<sub>2</sub> over O<sub>2</sub>, the enzyme must be highly selective—and the price of high selectivity is speed. CO<sub>2</sub> and O<sub>2</sub> are similar in size and chemical structure, and for this reason rubisco can achieve selectivity only by binding more tightly with the transition state ([Chapter 6](#)) of the carboxylation reaction. As a result, the better rubisco is at discriminating between CO<sub>2</sub> and O<sub>2</sub>, the slower its catalytic rate.

Nowhere is this trade-off more evident than in land plants, whose

photosynthetic cells acquire  $\text{CO}_2$  from an  $\text{O}_2$ -rich and  $\text{CO}_2$ -poor atmosphere. The rubiscos of plants are highly selective: if they are exposed to equal concentrations of  $\text{CO}_2$  and  $\text{O}_2$ , the ratio of  $\text{CO}_2$  addition to  $\text{O}_2$  addition is approximately 80:1. As a result, rubisco is a very slow enzyme, with catalytic rates on the order of three reactions per second. To put this rate in perspective, it is common for metabolic enzymes to achieve a catalytic rate of tens of thousands of reactions per second.

This trade-off between selectivity and speed is a key constraint for photosynthetic organisms. For plants, rubisco's low catalytic rate means that photosynthetic cells must produce huge amounts of this enzyme. As much as 50% of the total protein within a leaf is rubisco, and it is estimated to be the most abundant protein on Earth. At the same time, because  $\text{O}_2$  is approximately 500 times more abundant in the atmosphere than  $\text{CO}_2$ , as much as one-quarter of the reduced carbon formed in photosynthesis can be lost through photorespiration.

## Photosynthesis captures just a small percentage of incoming solar energy.

Typically, only 1% to 2% of the sun's energy that lands on a leaf ends up in carbohydrates. Does this mean that photosynthesis is incredibly wasteful? Or is this process, which is the product of billions of years of evolution, surprisingly efficient? This is not an idle question.

Photosynthesis is relevant to solving several pressing global issues: the effects of rising  $\text{CO}_2$  concentrations on Earth's climate; the search for renewable, carbon-neutral fuels to power our transportation sectors; and the agricultural demands of our skyrocketing human population.

Photosynthetic efficiency is typically calculated relative to the total energy output of the sun ([Fig. 8.18](#)). However, only visible light has the appropriate energy levels to raise the energy state of electrons in chlorophyll. Most of the sun's output (~60%) is not absorbed by chlorophyll and thus cannot be used in photosynthesis. In addition, leaves are not perfect at absorbing visible light—about 8% is either reflected or passes through the leaf. Finally, even under the best conditions, not all of the light energy absorbed by chlorophyll is transferred to the reaction center; some is given off as heat (also ~8%). This percentage increases when light levels are high, because excess light is actively converted into heat by xanthophyll pigments.

FIG. 8.18 Photosynthetic efficiency. Maximum photosynthetic efficiency is theoretically about 4% of incoming solar energy, but actual yields are closer to 1% to 2%.

---

The photosynthetic electron transport chain therefore captures, at most, about 24% of the sun's usable energy arriving at the surface of a leaf ( $100\% - 60\% - 8\% - 8\% = 24\%$ ). Although this number may appear low, it is on a par with the efficiency of high-performance photovoltaic cells in solar panels, which convert sunlight into electricity. However, energy is also lost at a later step. The incorporation of  $\text{CO}_2$  into carbohydrates results in considerable energy loss—equivalent to about 20% of the total incoming solar radiation. Some of this energy loss is due to photorespiration.

In total, the maximum energy conversion efficiency of photosynthesis is calculated to be around 4% ( $24\% - 20\%$ ). Efficiencies achieved by real plants growing in nature, however, are typically much lower, on the order of 1% to 2%. In Chapter 27, we explore the many factors that can constrain the photosynthetic output of plants and see how some plants have evolved ways to minimize losses in productivity due to drought and photorespiration.

#### Self-Assessment Questions

11. What are two strategies that plants use to limit the formation and effects of reactive oxygen species?
12. How is photorespiration similar to cellular respiration and how does it differ?
13. Why does rubisco have such a low catalytic rate (that is, why is it so slow)?
14. What is the overall efficiency of photosynthesis, and where in the

pathway is energy dissipated?

## 8.5 THE EVOLUTION OF PHOTOSYNTHESIS

The evolution of photosynthesis had a profound impact on the history of life on Earth. Not only did photosynthesis provide organisms with a new source of energy, but it also released oxygen into the atmosphere. As discussed in the previous chapter, evolution often works in a stepwise fashion, building on what is already present. Here, we consider hypotheses for how the photosynthetic pathways that are the dominant entry point for energy into the biosphere today may have evolved.

CASE 1 LIFE'S ORIGINS: INFORMATION, HOMEOSTASIS, AND ENERGY

### How did early cells use sunlight to meet their energy requirements?

Sunlight is a valuable source of energy, but it can also cause damage. Ultraviolet wavelengths, in particular, can damage DNA and other macromolecules. Thus, the earliest interactions with sunlight may have been the evolution of UV-absorbing compounds that could shield cells from the sun's damaging rays. Over time, random mutations could have produced chemical variants of these UV-absorbing molecules. One or more of these variant compounds might have been capable of using sunlight to meet the energy needs of the cell, perhaps by transferring electrons to another molecule as a present-day reaction

center does.

The earliest reaction centers may have used light energy to drive the movement of electrons from an electron donor outside the cell in the surrounding medium to an electron-acceptor molecule within the cell. In this way, energy from sunlight could have been used to synthesize carbohydrates. The first electron donor could have been a soluble inorganic ion like reduced iron,  $\text{Fe}^{2+}$ , which is thought to have been abundant in the early ocean. Alternatively, the first forms of light-driven electron transport may have been cyclic and thus did not require an electron donor. In either configuration, light-driven electron transport could have been coupled to the net movement of protons across the membrane, allowing for the synthesis of ATP.

Similarly, it is unlikely that these first photosynthetic organisms employed chlorophyll as a means of absorbing sunlight for the simple reason that the biosynthetic pathway for chlorophyll is complex, consisting of at least 17 enzymatic steps. Yet some of the intermediate compounds leading to chlorophyll are actually capable of absorbing light. Perhaps each of these now-intermediate compounds was, at one time, a functional end product used as a pigment by an early photosynthetic organism. The biosynthetic pathway may have gained steps as chemical variants produced by random mutations were selected because they were more efficient or more able to absorb new portions of the visible spectrum. Selection would have eventually resulted in the chlorophyll pigments that are used by photosynthetic organisms today.

The ability to use water as an electron donor in photosynthesis evolved

in cyanobacteria.

The most ancient forms of photosynthesis have only a single photosystem in their photosynthetic electron transport chains. As we have seen, a single photosystem cannot capture enough energy from sunlight to both pull electrons from water as well as raise their energy level enough that they can be used to reduce  $\text{CO}_2$ . Instead, photosynthetic organisms with a single photosystem must use more easily oxidized compounds, such as hydrogen sulfide ( $\text{H}_2\text{S}$ ), as electron donors. These organisms can exist only in environments where the electron-donor molecules are abundant. Because these organisms do not use water as an electron donor, they do not produce  $\text{O}_2$  during photosynthesis.

A major event in the history of life was the evolution of photosynthetic electron transport chains that use water as an electron donor. The first organisms to accomplish this feat were the cyanobacteria. These photosynthetic bacteria incorporated two different photosystems into a single photosynthetic electron transport chain: one to pull electrons from water molecules and one to raise the energy level of the electrons so that they can be used to reduce  $\text{CO}_2$ .

How did cyanobacteria end up with two photosystems? We cannot say for sure, but one clue is that each of the two photosystems present in cyanobacteria is similar in structure to photosystems found in groups of photosynthetic bacteria that contain only a single photosystem. Thus, it is highly unlikely that the photosystems in cyanobacteria evolved independently. One hypothesis is that the genetic material associated with one photosystem was transferred to a bacterium that

already had the other photosystem, resulting in a single bacterium with the genetic material to produce both types of photosystems (shown on the left in [Fig. 8.19](#)). The mechanisms by which genetic material is transferred between bacteria are discussed more fully in Chapter 24. Another hypothesis is that the genetic material associated with one photosystem underwent duplication. Over time, one of the two photosystems diverged slightly in sequence and function through mutation and selection, giving rise to two distinct but related photosystems (shown on the right in [Fig. 8.19](#)). This mechanism, called duplication and divergence, is discussed more fully in [Chapter 14](#).

FIG. 8.19 The evolutionary history of photosynthesis. (a) Hypotheses for the origin of the two photosystems in cyanobacteria. (b) Later, by endosymbiosis, free-

living cyanobacteria became the chloroplasts of eukaryotic cells.

The ability to use water as an electron donor in photosynthesis had two major impacts on life on Earth. First, photosynthesis could now occur anywhere there was both sunlight and sufficient water for cells to survive. Second, water releases oxygen as it donates electrons. Before the evolution of oxygenic photosynthesis, little or no free oxygen existed in Earth's atmosphere. All the oxygen in Earth's atmosphere results from photosynthesis by organisms containing two photosystems.

**Eukaryotic organisms are believed to have gained photosynthesis by endosymbiosis.**

Photosynthesis is hypothesized to have gained a foothold among eukaryotic organisms when a free-living cyanobacterium took up residence inside a eukaryotic cell ([Fig. 8.19](#)). Over time, the cyanobacterium lost its ability to survive outside its host cell and evolved into the chloroplast. The outer membrane of the chloroplast is thought to have originated from the plasma membrane of the ancestral eukaryotic cell, which surrounded the ancestral cyanobacterium as it became incorporated into the cytoplasm of the eukaryotic cell. The inner chloroplast membrane is thought to correspond to the plasma membrane of the ancestral free-living cyanobacterium. The thylakoid membrane then corresponds to the internal photosynthetic membrane found in cyanobacteria. Finally, the stroma corresponds to the cytoplasm of the ancestral cyanobacterium.

The process in which one cell takes up residence inside of another

cell is called endosymbiosis. Therefore, the idea that chloroplasts and mitochondria arose in this way is called the endosymbiotic hypothesis. It is discussed in Chapter 25.

Cellular respiration and photosynthesis are complementary metabolic processes. Cellular respiration breaks down carbohydrates in the presence of oxygen to supply the energy needs of the cell and produces carbon dioxide and water as by-products, whereas photosynthesis uses carbon dioxide and water in the presence of sunlight to build carbohydrates and releases oxygen as a by-product. We summarize the two processes in [Fig. 8.20](#).

FIG. 8.20 VISUAL SYNTHESIS Harnessing Energy: Photosynthesis and Cellular Respiration Integrating concepts from [Chapters 6–8](#)

### Self-Assessment Questions

15. What are two hypotheses to explain how cyanobacteria ended up

with two photosystems?

16. What are three major steps in the evolutionary history of photosynthesis?

## CORE CONCEPTS SUMMARY

**8.1 AN OVERVIEW OF PHOTOSYNTHESIS:** Photosynthesis is the major pathway by which energy and carbon are incorporated into carbohydrates.

In photosynthesis, water is oxidized, releasing oxygen, and carbon dioxide is reduced, forming carbohydrates. [page 158](#)

Photosynthesis consists of two sets of reactions: (1) the Calvin cycle, in which carbon dioxide is reduced to form carbohydrates, and (2) light-harvesting reactions, in which ATP and NADPH are generated to drive the Calvin cycle. [page 159](#)

In eukaryotes, photosynthesis takes place in chloroplasts: The Calvin cycle takes place in the stroma, and the light-harvesting reactions take place in the thylakoid membrane. [page 160](#)

**8.2 THE CALVIN CYCLE:** The Calvin cycle is a three-step process that uses carbon dioxide to synthesize carbohydrates.

The three steps of the Calvin cycle are (1) carboxylation; (2) reduction; and (3) regeneration. [page 160](#)

The first step is the addition of  $\text{CO}_2$  to the 5-carbon sugar RuBP. This step is catalyzed by the enzyme rubisco, considered the most abundant protein on Earth. [page 160](#)

The second step is the input of energy captured by sunlight. It begins with the donation of a phosphate group by ATP, followed by the transfer of electrons from NADPH to produce 3-carbon triose

phosphate molecules. Some of these triose phosphates are exported from the chloroplast to the cytosol. [page 161](#)

The third step is the regeneration of RuBP from five 3-carbon triose phosphates. [page 163](#)

Starch formation provides chloroplasts with a way of storing carbohydrates that will not cause water to enter the cell by osmosis. [page 163](#)

**8.3 CAPTURING SUNLIGHT INTO CHEMICAL FORMS:** The light-harvesting reactions use sunlight to produce the ATP and NADPH required by the Calvin cycle.

Chlorophyll absorbs visible light. [page 164](#)

Antenna chlorophyll molecules transfer absorbed light energy to the reaction center. [page 165](#)

Reaction centers are located within pigment–protein complexes known as photosystems. Special chlorophyll molecules in the reaction center transfer excited-state electrons to an electron-acceptor molecule, thus initiating the photosynthetic electron transport chain. [page 165](#)

The electron transport chain consists of a series of electron transfer or redox reactions that take place within both protein complexes and diffusible compounds. Water is the electron donor and  $\text{NADP}^+$  is the final electron acceptor. [page 166](#)

The linear transport of electrons from water to NADPH requires the energy input of two photosystems. [page 166](#)

Photosystem II pulls electrons from water, resulting in the production of oxygen and protons on the lumen side of the membrane. Photosystem I passes electrons to ferredoxin, which then reduces  $\text{NADP}^+$ , producing NADPH for use in the Calvin cycle. [page 167](#)

The movement of electrons through the electron transport chain is coupled with the transfer of protons from the stroma to the lumen. [page 169](#)

The buildup of protons in the lumen drives the production of ATP by oxidative phosphorylation. The ATP synthase is oriented such that ATP is produced on the stroma side of the membrane. [page 169](#)

Cyclic electron transport increases ATP production by redirecting electrons from ferredoxin back into the electron transport chain. [page 169](#)

**8.4 PHOTOSYNTHETIC CHALLENGES:** Challenges to the efficiency of photosynthesis include excess light energy and the oxygenase activity of rubisco.

An imbalance between the light-harvesting reactions and the Calvin cycle can lead to the formation of reactive oxygen species. [page 170](#)

Protection from excess light energy includes antioxidant molecules that neutralize reactive oxygen species and xanthophyll pigments that dissipate excess light energy as heat. [page 171](#)

Rubisco can act catalytically on oxygen as well as on carbon

dioxide. When it acts on oxygen, energy is lost and  $\text{CO}_2$  is released. [page 171](#)

Rubisco has evolved to favor carbon dioxide over oxygen, but the cost of this selectivity is reduced speed. [page 171](#)

The synthesis of carbohydrates through the Calvin cycle results in significant energy losses, which are due in part to photorespiration. [page 171](#)

The maximum theoretical efficiency of photosynthesis is approximately 4% of total incoming solar energy. [page 172](#)

**8.5 THE EVOLUTION OF PHOTOSYNTHESIS:** The evolution of photosynthesis had a profound impact on life on Earth.

The ability to use water as an electron donor in photosynthesis evolved in cyanobacteria. [page 174](#)

Cyanobacteria evolved two photosystems either by the transfer of genetic material or by gene duplication and divergence. [page 174](#)

Photosynthesis in eukaryotes likely evolved by endosymbiosis. [page 174](#)

All of the oxygen in Earth's atmosphere results from photosynthesis by organisms containing two photosystems. [page 174](#)

---

## CASE 2

### Cancer

#### *Cell Signaling, Form, and Division*

Imagine a simple vaccine that could prevent about 500,000 cases of cancer worldwide every year. You'd think such a discovery would be hailed as a miracle. Not quite. A vaccine to prevent cervical cancer, which affects about half a million women and kills as many as 275,000 annually, has been available since 2006. In the United States, however, this vaccine (and others) has stirred controversy.

Cancer is uncontrolled cell division. Cell division is a normal process that occurs during development of a multicellular organism and subsequently as part of the maintenance and repair of adult tissues. It is carefully regulated so that it occurs only at the right time and place. Sometimes, however, this careful regulation can be disrupted. When the normal checks on cell division become derailed, cancer can result.

*When the normal checks on cell division become derailed, cancer can result.*

Most cancers are caused by inherited or acquired mutations, but some are caused by viruses. In fact, nearly all cases of

cervical cancer are caused by a virus called human papillomavirus (HPV). There are hundreds of strains of HPV. Some of these strains cause minor problems such as common warts and plantar warts. Other strains are sexually transmitted. Some can cause genital warts but aren't associated with cancer. However, a handful of "high-risk" HPV strains are strongly tied to cancer of the cervix. More than 99% of cervical cancer cases are believed to arise from HPV infections.

HPV infects epithelial cells, a type of cell that lines the body cavities and covers the outer surface of the body. Once inside a cell, the virus hijacks the cellular machinery to produce new viruses. The high-risk strains of HPV that infect the cervix go one step further: those viruses that aren't fought off by the immune system can permanently integrate their own eight-gene DNA sequence into the host cell's DNA.

Once integrated into the DNA of human epithelial cells, the virus produces the proteins E6 and E7. These viral proteins, in turn, inhibit two cellular proteins, p53 and Rb, respectively. Both of these proteins are tumor suppressors. Tumor suppressors prevent cell division in healthy cells when DNA damage occurs or in other circumstances when cell division is harmful. In the presence of E6 and E7, p53 and Rb are unable to put the brakes on cell division, so cervical cells divide uncontrollably and cancer can result.

As they grow and multiply, the abnormal cells push through the basal lamina, a thin layer that separates the epithelial cells lining the cervix from the connective tissue beneath. Untreated, invasive cancer

can spread to other organs. Once cancer travels beyond its primary location, the situation is grim. Most cancers cannot be cured after they have spread.

Human papillomavirus (HPV) and cervical cancer. Certain strains of HPV can infect epithelial cells of the cervix and lead to cancer, which can spread to the rest of the body.

The U.S. Food and Drug Administration (FDA) has approved two

vaccines for HPV, both of which protect against the high-risk strains responsible for cervical cancer. Medical groups such as the American Academy of Pediatrics and government organizations such as the Centers for Disease Control and Prevention (CDC) recommend vaccinating girls at age 11 or 12, before they become sexually active. In addition, recent CDC guidelines also recommend vaccinating boys because they can transmit the virus to women when they become sexually active. On the basis of these recommendations, many states are considering legislation that would require middle-school girls to receive the vaccine.

However, there are critics of these recommendations and mandates. Some say the government shouldn't be making medical decisions. Others argue that the use of the vaccine encourages sexual activity among young girls and boys. Still others have expressed concern over the vaccine's safety.

Studies have found the HPV vaccine to be safe, a conclusion backed by a 2010 report from the Institute of Medicine, an independent nonprofit organization that advises the U.S government on issues of health. In addition, after 10 years of use, the HPV vaccine has reduced the number of cases of cervical cancer by half. Despite these findings, the HPV vaccine is slow to be accepted in the United States. The CDC found that by 2010, a full 5 years after the vaccine was introduced, only 32% of teenage girls had been fully vaccinated. In 2016, the percentage increased to 50%. Vaccination rates are lower in teenage boys compared to those of teenage girls; in 2016, 38% of teenage boys had been fully vaccinated.

Proponents of HPV vaccination say those numbers should cause concern. HPV is common: a 2007 study found that nearly 27% of American women ages 14–59 were infected with the virus. Among 20- to 24-year-olds, the infection rate was nearly 45%. Certainly, not everyone who contracts HPV will develop cancer. Most people manage to clear the virus from their bodies within 2 years of infection. In some cases, however, the virus hangs on and cancer results.

Because cancer is often difficult to treat, especially in its later stages, many researchers focus on early detection or prevention. Cervical cancer can be detected early by routine Pap smears, in which cells from the cervix are collected and observed under a microscope. As we have seen, cervical cancer can be prevented with a conventional vaccine. However, most cancers are not caused by viruses, and developing vaccines to prevent those cancers is a trickier proposition—but researchers are pushing ahead.

At the Mayo Clinic in Rochester, Minnesota, researchers are working to design vaccines to prevent breast and ovarian cancers from recurring in women who have been treated for these diseases. The researchers have zeroed in on proteins on the surface of cancerous cells. Cells communicate with one another by releasing signaling molecules that are picked up by receptor molecules on another cell's surface, much the way a radio antenna picks up a signal. Cellular communication is critical for a functioning organism. Sometimes, though, the signaling process goes awry.

The Mayo Clinic team is focusing on two cell-surface receptors that,

when malfunctioning, lead to cancer. One, Her2/neu, promotes the growth of aggressive breast cancer cells. The other, folate receptor  $\alpha$  (alpha) protein, is frequently overexpressed in breast and ovarian tumors. The researchers hope to train patients' immune systems to generate antibodies that recognize these proteins, and then destroy the cancerous cells. The approach has successfully prevented tumors in mice. Currently, the researchers are testing the vaccines in humans.

Even if these new therapies are successful, cancer researchers have much more work to do. Cancer is not one disease but many, and most cancers are caused by a complex interplay of genetic and environmental factors. Many things can go wrong as cells communicate, grow, and divide. However, as researchers learn more about the cellular processes involved, they can step in to prevent or treat cancer. As the HPV vaccine shows, there is significant progress to be made.

## DELVING DEEPER INTO CASE 2

**For each of the Cases, we provide a set of questions to pique your curiosity. These questions cannot be answered directly from the case itself, but instead introduce issues that will be addressed in chapters to come. We revisit this case in [Chapters 9–11](#) on the pages indicated below.**

1. How do cell signaling errors lead to cancer? See [page 198](#).
2. How do cancer cells spread throughout the body? See [page 219](#).

3. Which genes are involved in cancer? See [page 245](#).

## CHAPTER 9 Cell Signaling

Quest/Science Source

### CORE CONCEPTS

**9.1 PRINCIPLES OF CELL SIGNALING:** Cells communicate primarily by sending and receiving chemical signals.

**9.2 DISTANCE BETWEEN CELLS:** Cells communicate over long and short distances.

**9.3 SIGNALING RECEPTORS:** Signaling molecules bind to and activate cell-surface and intracellular receptors.

**9.4 G PROTEIN-COUPLED RECEPTORS:** G protein-coupled receptors are a large, conserved family of receptors that often lead to short-term responses, such as activating enzymes or opening ion channels.

**9.5 RECEPTOR KINASES:** Receptor kinases are widespread and often lead to long-term responses, such as changes in gene expression.

---

Up to this point, we have considered how life works by looking mainly at what happens inside individual cells. We have seen how a cell uses the information coded in genes to synthesize the proteins necessary to carry out diverse functions. We have also seen how the plasma membrane actively keeps the environment inside the cell different from the environment outside it. Finally, we have explored how a cell harvests and uses energy from the environment.

In the next three chapters, we zoom out from individual cells and consider cells in context. Cells always exist in a particular environment, and their behavior is often strongly influenced by this environment. For example, the environment of unicellular organisms consists of their physical surroundings and other cells nearby. The ability of cells to sense and respond to this environment is critical for survival. A unicellular organism senses information that signals it when to feed, when to move, and when to divide.

In multicellular organisms, cells do not exist by themselves, but instead are part of cellular communities. These cells may physically adhere to one another, forming tissues and organs. Often multicellular organisms are highly complex, made up of cells of many types with specialized functions. These cells respond to signals, which may come from the outside environment or from other cells of the organism. Cell communication helps to coordinate the activities of the thousands, millions, and trillions of cells that make up the organism. These cells all come about through the process of cell division. Cells divide as part of growth and development, as well as tissue maintenance and repair. Cell division is an example of a cellular activity that is often regulated by signals—in this case, the signals tell a cell when to start dividing and when to stop dividing.

In [Chapter 9](#), we look at how cells send, receive, and respond to signals. In [Chapter 10](#), we focus on how cells maintain their shape and, in some cases, physically adhere to one another. As we saw in the case of molecules, form is inextricably linked to function. Finally, in [Chapter 11](#), we consider how one cell becomes two through the process of cell division.

# 9.1 PRINCIPLES OF CELL SIGNALING

The activities of virtually all cells are influenced by their surroundings. Cells receive large amounts of information from numerous sources in their surroundings. One key source of information is the physical environment. Another is other cells—neighboring cells, nearby cells, and even very distant cells. Both unicellular and multicellular organisms sense information from their surroundings and respond to that information by changing their activity or even dividing.

In this section, we consider the general principles of cell communication, including how cells send and receive signals and how a cell responds after it receives a signal. These mechanisms first evolved in unicellular organisms as a way to sense and respond to their environment, and also as a way to influence the behavior and activity of other cells. These basic principles apply to all cells, both prokaryotic and eukaryotic, and to all organisms, both unicellular and multicellular.

## Cells communicate using chemical signals that bind to receptors.

Cellular communication consists of four essential elements: a [signaling cell](#), a [signaling molecule](#), a [receptor protein](#), and a [responding cell](#) ([Fig. 9.1](#)). The signaling cell is the source of a signaling molecule. Signaling molecules vary immensely and include peptides, lipids, and gases. In all cases, the signaling molecule carries information from one cell to the next. The signaling molecule binds to a receptor protein on or in the responding cell; in turn, the responding cell changes its

activity or behavior.

Let's consider a simple, all-too-familiar example. You're startled or scared, and you experience a strange feeling in the pit of your stomach and your heart beats faster. Collectively, these physiological changes are known as the "fight or flight" response. For these changes to occur, a signal must go from signaling cells to responding cells in the heart, lungs, stomach, and many other organs ([Fig. 9.2](#)). This signal is the hormone adrenaline (also called epinephrine). In response to stress, adrenaline is released from the adrenal glands, located above the kidneys. Adrenaline circulates through the body and acts on many types of cells, including the cells of your heart, causing it to beat more strongly and quickly. As a result, the heart is able to deliver oxygen more effectively to the body.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 9.2 Communication among cells in a multicellular organism. Adrenaline binds to receptors on many cells in many organs, leading to the “fight or flight” response.

This example illustrates the four basic elements involved in cellular communication. In this case, the signaling cells are specific cells within the adrenal glands. The signaling molecule is the hormone adrenaline released by these cells. Adrenaline is carried in the bloodstream and binds to receptor proteins located on the surface of responding cells, like those of the heart.

Let’s look at a second example, this time focusing on communication among bacteria ([Fig. 9.3](#)). *Streptococcus pneumoniae* (also known as pneumococcus) is a bacterium that causes pneumonia, meningitis, and some kinds of arthritis. Many bacteria, including

pneumococci, are able to take up DNA from the environment and incorporate it into their genome ([Chapter 24](#)). By this means, individual bacterial cells can acquire genes with advantageous properties, including antibiotic resistance.

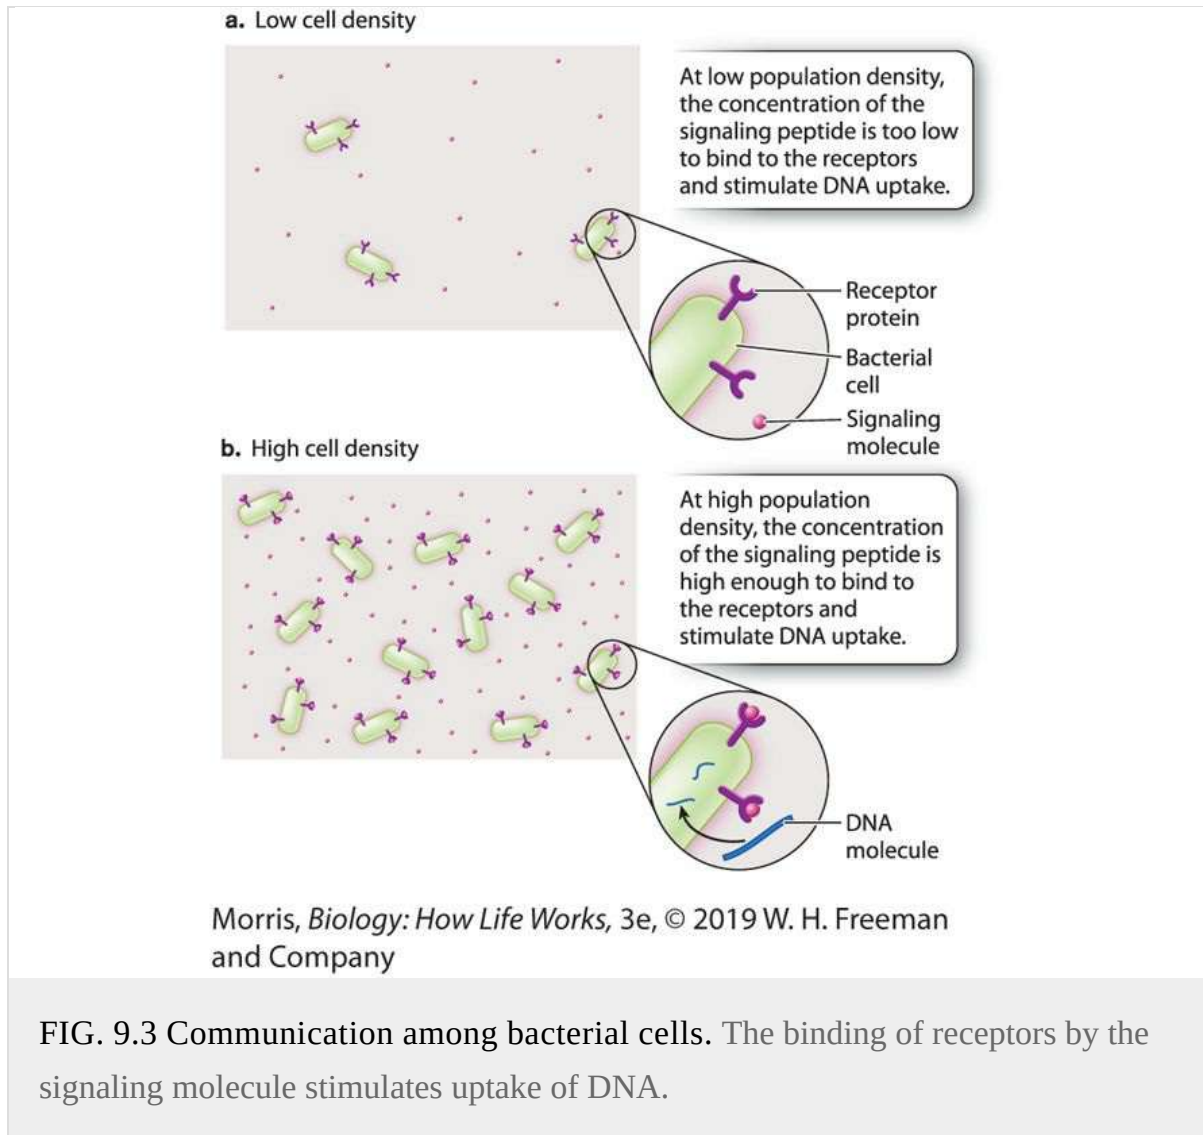

FIG. 9.3 Communication among bacterial cells. The binding of receptors by the signaling molecule stimulates uptake of DNA.

In the 1960s, it was observed that the rate of DNA uptake by pneumococcal cells increased sharply once the bacterial population reached a certain density. Scientists concluded that the bacteria were able to coordinate DNA uptake across the population so that it occurred only at high population density. How is it possible that these

bacteria “know” how many other bacteria are present? It turns out that they are able to communicate this information to one another through the release of a small peptide.

In the 1990s, scientists discovered a short peptide consisting of 17 amino acids that is continuously synthesized and released by pneumococcal cells. Not long after, a receptor for this peptide was discovered on the surface of these pneumococcal cells. The binding of this peptide to its receptor causes a bacterium to express the genes required for DNA uptake. When the bacteria are present at only a low density, the peptide is at too low a concentration to bind to the receptor ([Fig. 9.3a](#)). As the population density increases, so does the concentration of the peptide, until it reaches a level high enough that the peptide binds to enough receptors to cause the cells to turn on genes necessary for DNA uptake ([Fig. 9.3b](#)).

This is an example of quorum sensing, a process used by bacteria to determine whether they are at low or high population density and then turn on specific genes across the entire community. It is used to control and coordinate many different types of bacterial behaviors, such as bioluminescence, antibiotic production, and biofilm formation.

This example also illustrates the four essential elements involved in communication between cells. In this case, each bacterial cell is both a signaling cell and a responding cell because each cell makes the signaling molecule and its receptor. The general idea that cells are able to communicate by sending a signaling molecule that binds to a receptor on a responding cell is universal among prokaryotes and

eukaryotes. These four elements act in very much the same way in myriad types of cellular communication.

## Signaling involves receptor activation, signal transduction, response, and termination.

What happens when a signaling molecule binds to a receptor on a responding cell? The first step is **receptor activation**. On binding the signal, the receptor is turned on, or activated (**Fig. 9.4**). The signal usually activates the receptor by causing a conformational change in the receptor. As a result, some receptors bind to and activate other proteins located inside the cell. Other receptors are themselves enzymes, and binding of the signal changes the shape and activity of the enzyme. Still other receptors are channels that open or close in response to binding a signaling molecule.

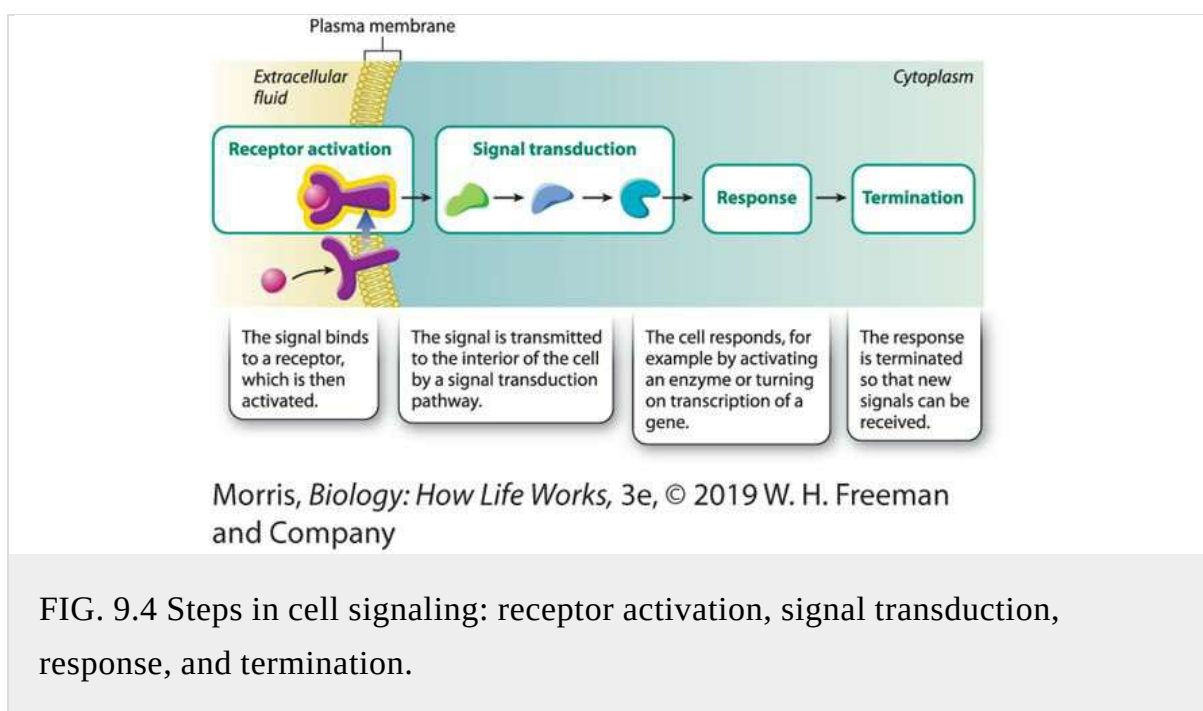

FIG. 9.4 Steps in cell signaling: receptor activation, signal transduction, response, and termination.

Once activated, the receptor often triggers a series of downstream events in a process called **signal transduction**. During signal transduction, one molecule activates the next molecule, which activates the next, and so on. In this way, signal transduction can be thought of as a chain reaction or cascade of biochemical events set off by the binding and activation of the receptor. An important aspect of signal transduction is that the signal is often amplified at each step in the pathway. As a result, a low signal concentration can have a large effect on the responding cell.

Next, there is a cellular **response**, which can take different forms depending on the nature of the signal and the type of responding cell. For example, signaling pathways can activate enzymes involved in metabolic pathways, or turn on genes that cause the cell to divide, change shape, or signal other cells.

The last step is **termination**, in which the cellular response is stopped. The response can be terminated at any point along the signaling pathway. Termination protects the cell from overreacting to existing signals, thereby helping the cell have an appropriate level of response. It also allows the cell to respond to new signals.

In the case of pneumococcal cells, the peptide binds to and activates a receptor on the cell surface. When enough receptors are bound by the signaling molecule, the message is relayed by signal transduction pathways to the nucleoid. There, genes are turned on that express proteins involved in DNA uptake from the environment. Eventually, when the density of bacteria is low, the initiating signal falls below a

critical threshold and gene expression is turned back off.

This example is relatively simple. Remarkably, other more complex signaling pathways in a wide range of organisms involve the same four elements and steps. Indeed, in many cases they utilize similar signaling molecules, receptors, and signal transduction systems that have been evolutionarily conserved over long periods of time.

## The response of a cell to a signaling molecule depends on the cell type.

Cells are typically exposed to many different types of signaling molecules. What determines whether a cell responds to a signaling molecule? A cell responds to a signal only if it has receptors that are able to bind to the signaling molecule. If specific receptors are present, binding of a signaling molecule leads to downstream effects; if they are not, the cell is not able to respond. In the case of adrenaline, only cells with receptors for adrenaline are able to respond. Adrenaline receptors are widespread in the body, including in the heart, lungs, stomach, and many other organs. The presence of these receptors allows cells of these organs to respond to adrenaline.

When a signaling molecule binds to a receptor, what determines the specific response of the cell? The cell's response depends on the set of proteins that is found in the cell, as different cell types have different sets of intracellular proteins and signaling pathways. As a result, the same signaling molecule can have different effects in different types of cells. Adrenaline, for example, can cause heart muscle cells to contract more quickly and forcefully, whereas it causes cells lining the airways

of the lung to relax.

#### Self-Assessment Questions

1. What are the four essential elements of cell signaling?
2. What are the steps that occur when a signaling molecule binds to a receptor on a responding cell?
3. If a hormone is released into the bloodstream so that it comes into contact with many cells, what determines which cells in the body respond to the hormone?

## 9.2 DISTANCE BETWEEN CELLS

In prokaryotes and unicellular eukaryotes, cell communication occurs between individual organisms. In complex multicellular eukaryotes, cell communication occurs between cells within the same organism. The same principles apply in both instances, although some important differences exist. In multicellular organisms, the distance between communicating cells varies considerably. When the two cells are far apart, the signaling molecule is transported by the circulatory system. When they are close, the signaling molecule simply moves by diffusion. In addition, many cells in multicellular organisms are physically attached to one another, in which case the signaling molecule is not released from the signaling cell at all. In this section, we explore communication over long and short distances, as well as communication between cells that are physically attached to one another.

### Endocrine signaling acts over long distances.

Signaling molecules released by a cell may have to travel great distances to reach receptor cells in the body. In such a case, they are often carried in the circulatory system. Signaling by means of molecules that travel through the bloodstream is called **endocrine signaling** ([Fig. 9.5a](#); [Chapter 36](#)).

Adrenaline ([section 9.1](#)) provides a good example of endocrine signaling. Adrenaline is produced in the adrenal glands, and then carried by the bloodstream to target cells that are far from the signaling cells. Other examples of endocrine signaling involve the mammalian steroid hormones estradiol (an estrogen) and testosterone (an androgen). These hormones travel from the ovaries and the testes, respectively (although there are other minor sources of these hormones), through the bloodstream, to target cells in various tissues throughout the body. The increased amount of estrogen in girls during puberty causes the development of breast tissue and the beginning of menstrual cycles. The increased amount of testosterone in boys during puberty causes the growth of muscle cells, deepening of the voice, and growth of facial hair ([Chapter 40](#)).

## Signaling can occur over short

## distances.

Signaling can also occur between two cells that are close to each other (**Fig. 9.5b**). In this case, movement of the signaling molecule through the circulatory system is not needed. Instead, the signaling molecule can simply move by diffusion between the two cells. This form of signaling is called **paracrine signaling**. Paracrine signaling molecules travel distances of approximately 20 cell diameters, or a few hundred micrometers.

In paracrine signaling, the signal usually takes the form of a small, water-soluble molecule such as a **growth factor**. A growth factor is a type of signaling molecule that causes the responding cell to grow, divide, or differentiate. One of the first growth factors discovered was found by scientists who were attempting to understand how to maintain cultures of cells in the laboratory. For decades, medical research has worked with cells maintained in culture. Initially, these cultured cells had limited use because they failed to divide outside the body unless they were supplied with unidentified factors from mammalian blood serum. In 1974, American scientists Nancy Kohler and Allan Lipton discovered that one of these factors is secreted by platelets, leading it to be named platelet-derived growth factor (PDGF) (**Fig. 9.6**). We now know of scores of molecules secreted by cells that function as growth factors; in most cases, their effects are confined to neighboring cells.

### HOW DO WE KNOW?

## FIG. 9.6

Where do growth factors come from?

## BACKGROUND

Cells grown outside the body in culture survive and grow well only under certain conditions. For a long time, researchers hypothesized that certain substances are required for cells to grow in culture, but the identity and source of these substances remained a mystery. A key insight came from the observation that chicken cells grow much better if they are cultured in blood serum rather than in blood plasma. Blood serum is the liquid component of blood that is collected after blood has been allowed to clot. Blood plasma is also the liquid component of blood, but it is collected from blood that has not clotted. In the 1970s, American biologists Nancy Kohler and Allan Lipton were interested in identifying the source of the factor in blood serum (that is not present in blood plasma) that allows cells to survive in culture.

## HYPOTHESIS

Kohler and Lipton knew that clotting depends on the release of substances from platelets. Because cells grow better in serum (which has been allowed to clot) compared to plasma (which has not clotted), they hypothesized that a growth-promoting factor was released by platelets during clotting.

## EXPERIMENT 1 AND RESULTS

The researchers first confirmed earlier observations using mouse cells called fibroblasts that are easily grown in culture. They grew two sets of fibroblasts in small plastic dishes. They added serum to one of the dishes and plasma to the other. They counted the number of cells in both culture dishes over time to determine the rate of cell division. Fibroblasts grown in serum divided more rapidly than those grown in plasma, as expected from earlier experiments ([Fig. 9.6a](#)).

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

#### EXPERIMENT 2 AND RESULTS

To see if the growth-promoting factor is released from platelets, the researchers prepared a solution of proteins made from purified platelets, added these proteins to cultured fibroblasts, and counted the number of cells over time. They found that fibroblasts grown in the presence of platelet proteins divided more rapidly than fibroblasts grown in plasma

(Fig. 9.6b).

#### CONCLUSION

Kohler and Lipton concluded that the growth-promoting factor is a protein that is released by platelets on clot formation, and that is normally present in serum but absent in plasma.

#### FOLLOW-UP WORK

Over the next few years, Kohler, Lipton, and other researchers purified and characterized the growth factor we know today as platelet-derived growth factor, or PDGF.

SOURCE Kohler, N., and A. Lipton. 1974. "Platelets as a Source of Fibroblast Growth-Promoting Activity." *Experimental Cell Research* 87:297–301.

Growth factors secreted by cells in an embryo work over short distances to influence the kind of cells their neighbors will become. In this way, they help shape the structure of the adult's tissues, organs,

and limbs. For example, in developing vertebrates, paracrine signaling by the growth factor Sonic Hedgehog (yes, it's named after a video game character) ensures that the motor neurons in your spinal cord are in the proper locations, that the bones of your vertebral column form correctly, and that your thumb and pinky fingers are on the correct sides of your hands.

A specialized form of short-range signaling is the communication between neurons (nerve cells), and between neurons and muscle cells ([Chapters 34](#) and [35](#)). Neurotransmitters are a type of signaling molecule released from a neuron. After release, they diffuse across a small space, called a synapse, between the signaling cell and the responding cell. If the adjacent cell is a neuron, it often responds by transmitting a nerve impulse and then releasing additional neurotransmitters. If the responding cell is a muscle cell, it may respond by contracting.

Sometimes signaling molecules may be released by a cell and then bind to receptors on the very same individual cell. Such cases, where signaling cell and responding cell are one and the same, are examples of **autocrine signaling** ([Fig. 9.5c](#)). Autocrine signaling is especially important to multicellular organisms during the development of the embryo ([Chapters 19](#) and [40](#)). For example, once a cell differentiates into a specialized cell type, autocrine signaling is sometimes used to maintain this developmental decision. In addition, autocrine signaling can be used by cancer cells to promote cell division.

## Signaling can occur by direct cell–cell

## contact.

Sometimes a cell communicates with another cell through direct contact, without diffusion or circulation of the signaling molecule. This form of signaling requires that the two communicating cells be in physical contact with each other. A transmembrane protein on the surface of one cell acts as the signaling molecule, and a transmembrane protein on the surface of an adjacent cell acts as the receptor ([Fig. 9.5d](#)). In this case, the signaling molecule is not released from the cell, but instead remains associated with the plasma membrane.

This form of signaling is important during embryonic development. As an example, consider the development of the central nervous system of vertebrate animals. In the brain and spinal cord, neurons transmit information in the form of electrical signals that travel from one part of the body to another. The neurons in the central nervous system are greatly outnumbered by supporting cells, called glial cells, which nourish and insulate the neurons. Both the neurons and the glial cells start out as similar cells in the embryo, but some of these undifferentiated cells become neurons and many more become glial cells.

During brain development, the amount of a transmembrane protein called Delta dramatically increases on the surface of some of these undifferentiated cells. These cells will become neurons. Delta proteins on each new neuron bind to transmembrane proteins called Notch on the surface of adjacent, undifferentiated cells. In this case, the signaling cell is the cell with elevated levels of Delta protein. The Delta protein, in turn, is the signaling molecule, and Notch is its receptor. Cells with

activated Notch receptors become glial cells and not neurons. Because one signaling cell sends this same message to all the cells it contacts, it is easy to understand how there can be so many more glial cells than neurons in the central nervous system.

As you can see from these examples, the same fundamental principles are at work when signaling guides a developing embryo, allows neurons to communicate with other neurons or muscles, triggers DNA uptake by pneumococcal cells, or allows your body to respond to stress. All of these forms of communication are based on signals that are sent from a signaling cell to a responding cell. These signaling molecules are the language of cellular communication.

#### Self-Assessment Questions

4. What is one way in which endocrine, paracrine, autocrine, and contact-dependent signaling are similar to one another?
5. What is one way in which endocrine, paracrine, autocrine, and contact-dependent signaling are different from one another?

## 9.3 SIGNALING RECEPTORS

Receptors are proteins that receive and interpret information carried by signaling molecules. Regardless of the distance between communicating cells, a responding cell receives a message when the signaling molecule binds to a receptor protein on or in that cell. For this reason, the signaling molecule is often referred to as a **ligand** (from the Latin *ligare*, which means “to bind”). The signaling molecule binds to a specific part of the receptor protein called the **ligand-binding site**. The bond formed is noncovalent and highly specific: the signaling molecule binds only to a receptor with a ligand-binding site that recognizes the molecule.

The binding of a signaling molecule to the ligand-binding site of a receptor typically causes a conformational change in the receptor. We say that the conformational change “activates” the receptor because it is through this change that the receptor passes the message from the signaling molecule to the interior of the cell. In many ways, this change in receptor shape is similar to the change that occurs when a substrate binds to the active site of an enzyme ([Chapter 6](#)). The conformational change in the receptor ultimately triggers chemical reactions or other changes in the cytosol, so it serves as a crucial step in the reception and interpretation of communications from other cells.

**Receptors for polar signaling molecules are located on the cell surface.**

The location of a particular receptor in a cell depends largely on

whether the signaling molecule is polar or nonpolar ([Fig. 9.7](#)). Many signaling molecules, such as the growth factors we just discussed, are small, polar proteins that cannot pass through the hydrophobic core of the plasma membrane. The receptor proteins for these signals are located on the outside surface of the responding cell ([Fig. 9.7a](#)).

FIG. 9.7 Cell-surface and intracellular receptors. (a) Cell-surface receptors interact with polar signaling molecules that cannot cross the plasma membrane. (b) Intracellular receptors interact with nonpolar signaling molecules that can cross the

Receptor proteins for growth factors and other polar ligands are transmembrane proteins with an extracellular domain, a transmembrane domain, and a cytoplasmic domain. When a signaling molecule binds to the ligand-binding site in the extracellular domain, the entire molecule, including the cytoplasmic domain of the receptor, undergoes a conformational change, and as a result the molecule is activated. In this way, the receptor acts as a bridge between the inside and the outside of the responding cell that carries the message of the hydrophilic signal across the hydrophobic core of the plasma membrane.

## Receptors for nonpolar signaling molecules are located in the interior of the cell.

The receptors for nonpolar signaling molecules, such as the steroid hormones involved in endocrine signaling, are not located on the surface of the cell. Since steroids are hydrophobic, they pass easily through the hydrophobic core of the phospholipid bilayer and into the target cell. Once inside, steroid hormones bind to receptor proteins located in the cytosol or in the nucleus to form receptor–steroid complexes ([Fig. 9.7b](#)). Steroid–receptor complexes formed in the cytosol enter the nucleus, where they act to control the expression of specific genes. Steroid receptors located in the nucleus are often already bound to DNA and need only to bind to their steroid counterpart to turn on gene expression.

Many examples of steroid hormones exist, including sex hormones, glucocorticoids (which raise blood glucose levels), and ecdysone (involved in insect molting). However, because much of the information received by cells is transmitted across the plasma membrane through transmembrane receptors, we focus our attention here on the sequence of events that takes place when receptors on the surface of cells bind their ligands.

## Cell-surface receptors act like molecular switches.

As we saw earlier, a receptor is activated after a signaling molecule binds to its ligand-binding site. Many receptors act as binary molecular switches, existing in two alternative states, either “on” or “off” ([Fig. 9.8](#)). In this way, receptors behave similarly to a light switch ([Fig. 9.8a](#)). When bound to their signaling molecule, the molecular switch is turned on. When the signaling molecule is no longer bound, the switch is turned off.

FIG. 9.8 Three types of cell-surface receptors. (a) Receptors act like a light

switch. (b) G protein-coupled receptors, (c) receptor kinases, and (d) ligand-gated ion channels can be either “off” (inactive) or “on” (active).

Thousands of different receptor proteins are present on the surface of any given cell. Most of them can be placed into one of three groups on the basis of their structures and what occurs immediately after the receptor binds its ligand. One type of cell-surface receptor is called a **G protein-coupled receptor** (Fig. 9.8b; section 9.4). When a ligand binds to a G protein-coupled receptor, the receptor couples to, or associates with, a **G protein**, as its name suggests. G protein-coupled receptors are evolutionary conserved and all have a similar molecular structure.

A second group of cell-surface receptors are themselves enzymes, which become catalytically active when the receptor binds its ligand. Most of these are **receptor kinases** (Fig. 9.8c and section 9.5). A kinase is an enzyme that catalyzes the transfer of a phosphate group from ATP to a substrate. To catalyze this reaction, it binds both ATP and the substrate in a process called phosphorylation (Fig. 9.9). Phosphorylation is important because it alters the activity of the substrate: when a protein is phosphorylated by a kinase, it typically becomes active and is switched on. The addition of a phosphate group can activate a protein by altering its shape or providing a new site for other proteins to bind. **Phosphatases** remove a phosphate group, a process called dephosphorylation (Fig. 9.9). When a protein is dephosphorylated by a phosphatase, it typically becomes inactive and is switched off.

FIG. 9.9 Phosphorylation and dephosphorylation. A kinase transfers a phosphate group from ATP to a protein, typically activating the protein. A phosphatase removes a phosphate group from a protein, typically deactivating the protein.

Receptors in the third group, **ion channels**, alter the flow of ions across the plasma membrane. Recall from [Chapter 5](#) that channel proteins help ions and other molecules diffuse into and out of the cell by providing a hydrophilic pathway through the hydrophobic core of the plasma membrane. Most of the time, the channels are closed. However, when a signal arrives, the channel undergoes a conformational change that opens it and allows ions to flow in and out. These channels can be opened in different ways. Some open in response to changes in voltage across the membrane; these are called voltage-gated ion channels and are discussed in [Chapter 34](#). Other ion channels open when bound by their ligand; these are called ligand-gated ion channels ([Fig. 9.8d](#)) and are discussed in [Chapter 35](#).

Signaling using ion-channel receptors is especially important for nerve and muscle cells because their functions depend on a rapid change in ion flow across the plasma membrane.

What happens after a signaling molecule binds to its receptor and flips a molecular switch? Following receptor activation, signaling pathways transmit the signal to targets in the interior of the cell, the cell responds, and eventually the signal is terminated. In the next two sections, we examine the signaling pathways activated by G protein-coupled receptors and receptor kinases.

#### Self-Assessment Questions

6. How are receptors that bind polar and nonpolar signaling molecules similar, and how are they different?
7. How can cells respond to external signaling molecules, even when those signaling molecules cannot enter the cell?
8. What are three possible initial steps following the binding of a signaling molecule to a receptor?

## 9.4 G PROTEIN-COUPLED RECEPTORS

G protein-coupled receptors, introduced in [section 9.3](#), are a very large family of cell-surface molecules. They are found in almost every eukaryotic organism. In humans, for example, approximately 800 different G protein-coupled receptors have been identified. All of these receptors have three characteristics in common. First, they have a similar structure, consisting of a single polypeptide chain that has seven transmembrane spanning regions, with the ligand-binding site on the outside of the cell and the portion that binds to the G protein on the inside of the cell. Second, when activated, they associate with a G protein. In this way, they are able to transmit the signal from the outside to the inside of the cell. Third, the cellular responses to the activation of G protein-coupled receptors all tend to be rapid and short-lived. These characteristics result from their shared evolutionary history.

In spite of their similarity, different G protein-coupled receptors are able to respond to different signaling molecules. Hormones, neurotransmitters, and small molecules are among the diverse set of signaling molecules that bind to this group of receptors. In addition, the effects of these receptors are quite diverse. For example, signaling through these receptors is responsible for our senses of sight, smell, and taste ([Chapter 34](#)). In fact, it is thought that G protein-coupled receptors evolved from sensory receptors in unicellular eukaryotes.

**The first step in cell signaling is**

## receptor activation.

A G protein-coupled receptor can be inactive (off) or active (on) depending on whether it is bound to a ligand. In the absence of a ligand, it is inactive. When a ligand binds to a G protein-coupled receptor, the receptor is active. In its active state, it couples to (that is, it binds to) a G protein located on the cytoplasmic side of the plasma membrane.

The G protein also has two states, off or on. A G protein is able to bind to the guanine nucleotides GDP and GTP. When it is bound to GDP, it is off, or inactive; when it is bound to GTP, it is on, or active.

When a G protein-coupled receptor binds to a G protein, it activates the G protein by causing it to release GDP and bind GTP. As long as the G protein is bound to GTP, it is in the on position. The activated G protein goes on to activate additional proteins in the signaling pathway.

Some G proteins are composed of three subunits:  $\alpha$  (alpha),  $\beta$  (beta), and  $\gamma$  (gamma) ([Fig. 9.10](#)). The  $\alpha$  subunit is the part of the G protein that binds to either GDP or GTP. When GDP bound to the  $\alpha$  subunit is replaced by GTP, the  $\alpha$  subunit separates from the  $\beta$  and  $\gamma$  subunits. In most cases, the isolated GTP-bound  $\alpha$  subunit becomes active and is able to bind to target proteins in the cell.

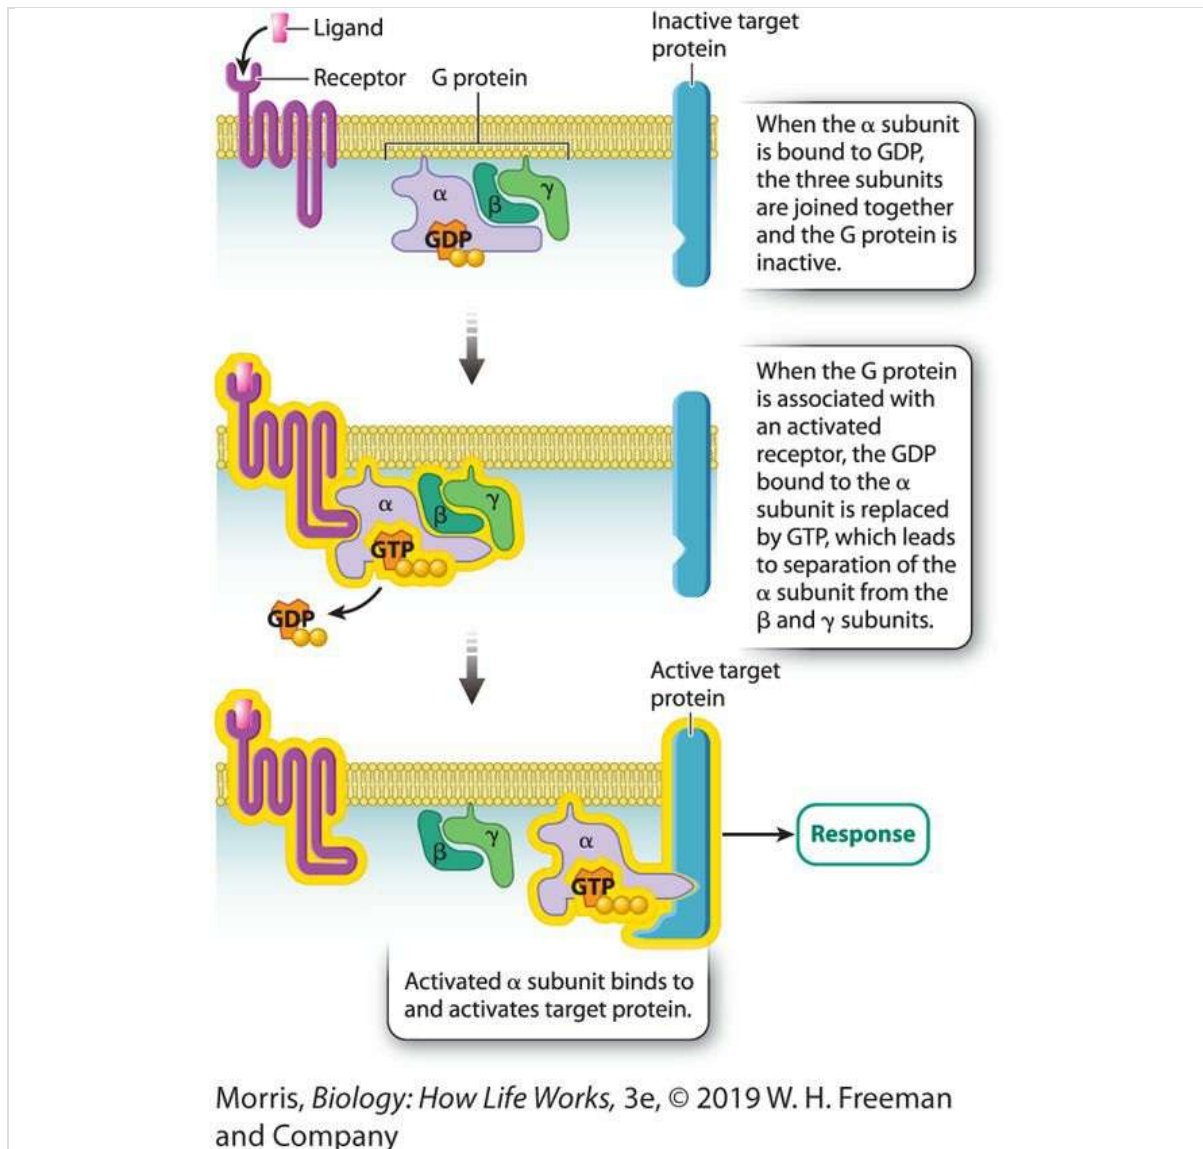

FIG. 9.10 Activation of a G protein by a G protein-coupled receptor. A G protein-coupled receptor is activated when it binds a signaling molecule, which leads to exchange of GDP for GTP on the G protein's  $\alpha$  subunit, separation of the  $\alpha$  subunit, and downstream effects.

## Signals are often amplified in the cytosol.

Let's follow the steps in cell signaling by examining a specific example. Adrenaline, discussed earlier, binds to a G protein-coupled receptor. When adrenaline binds to its receptor on cardiac muscle cells,

GDP in the G protein is replaced by GTP and the G protein is activated.

The GTP-bound  $\alpha$  subunit then binds to and activates an enzyme in the cell membrane called adenylyl cyclase ([Fig. 9.11](#)). Adenylyl cyclase converts the nucleotide ATP into cyclic AMP (cAMP). Cyclic AMP is known as a [second messenger](#). Second messengers are signaling molecules found inside cells that relay information to the next target in the signal transduction pathway. For example, the second messenger cAMP binds to and activates protein kinase A (PKA). The term “second messenger” was coined to differentiate these signaling molecules from those like adrenaline and growth factors, which are considered first messengers.

FIG. 9.11 Adrenaline signaling in heart muscle. Adrenaline binds to a G protein-coupled receptor, leading to production of the second messenger cAMP and activation of protein kinase A. The cell's response increases the heart rate.

A little adrenaline goes a long way as a result of signal amplification ([Fig. 9.12](#)). First, a single receptor bound to adrenaline can activate several G protein molecules. Next, each molecule of adenylyl cyclase catalyzes the production of large amounts of the second messenger cAMP. Then, each PKA molecule activates multiple protein targets by phosphorylation. These sequential molecular changes in the cytosol amplify the signal so that a very small amount of signaling molecule has a large effect on a responding cell.

FIG. 9.12 Amplification of G protein-coupled signaling. Signaling through G protein-coupled receptors is amplified at several places, so a small amount of signal can produce a large response in the cell.

## Signals lead to a cellular response.

As we have seen, the response of a cell to a signaling molecule depends on which type of cell it is and, therefore, which types of proteins are present within the cell. G protein-coupled receptors, for example, have different effects in different cell types. In the case of heart cells, activated PKA leads to the opening of calcium channels that are present in heart muscle cells. The resulting influx of calcium ions results in shorter intervals between muscle contractions, leading to a faster heart rate. As long as adrenaline is bound to its receptor, the heart rate remains rapid. The rapid heart rate, in turn, increases blood flow to the brain and skeletal muscles to deal with the stress that triggered the signal in the first place.

This example is typical of signaling through G protein-coupled receptors. These receptors tend to activate downstream enzymes or, in some cases, open ion channels. Because they often modify proteins that are already synthesized in the cell, their effects tend to be rapid, short-lived, and easily reversible, as we will see next.

## Signaling pathways are eventually terminated.

After a good scare, we eventually calm down and our heartbeat returns to normal. This change means that the signaling pathway initiated by

adrenaline has been terminated. How does this happen? First, most ligands, including adrenaline, do not bind to their receptors permanently. How long a signaling molecule remains bound to its receptor depends on how tightly the receptor holds on to it, a property called **binding affinity**. Once adrenaline leaves the receptor, the receptor reverts to its inactive conformation and no longer activates G proteins (**Fig. 9.13**).

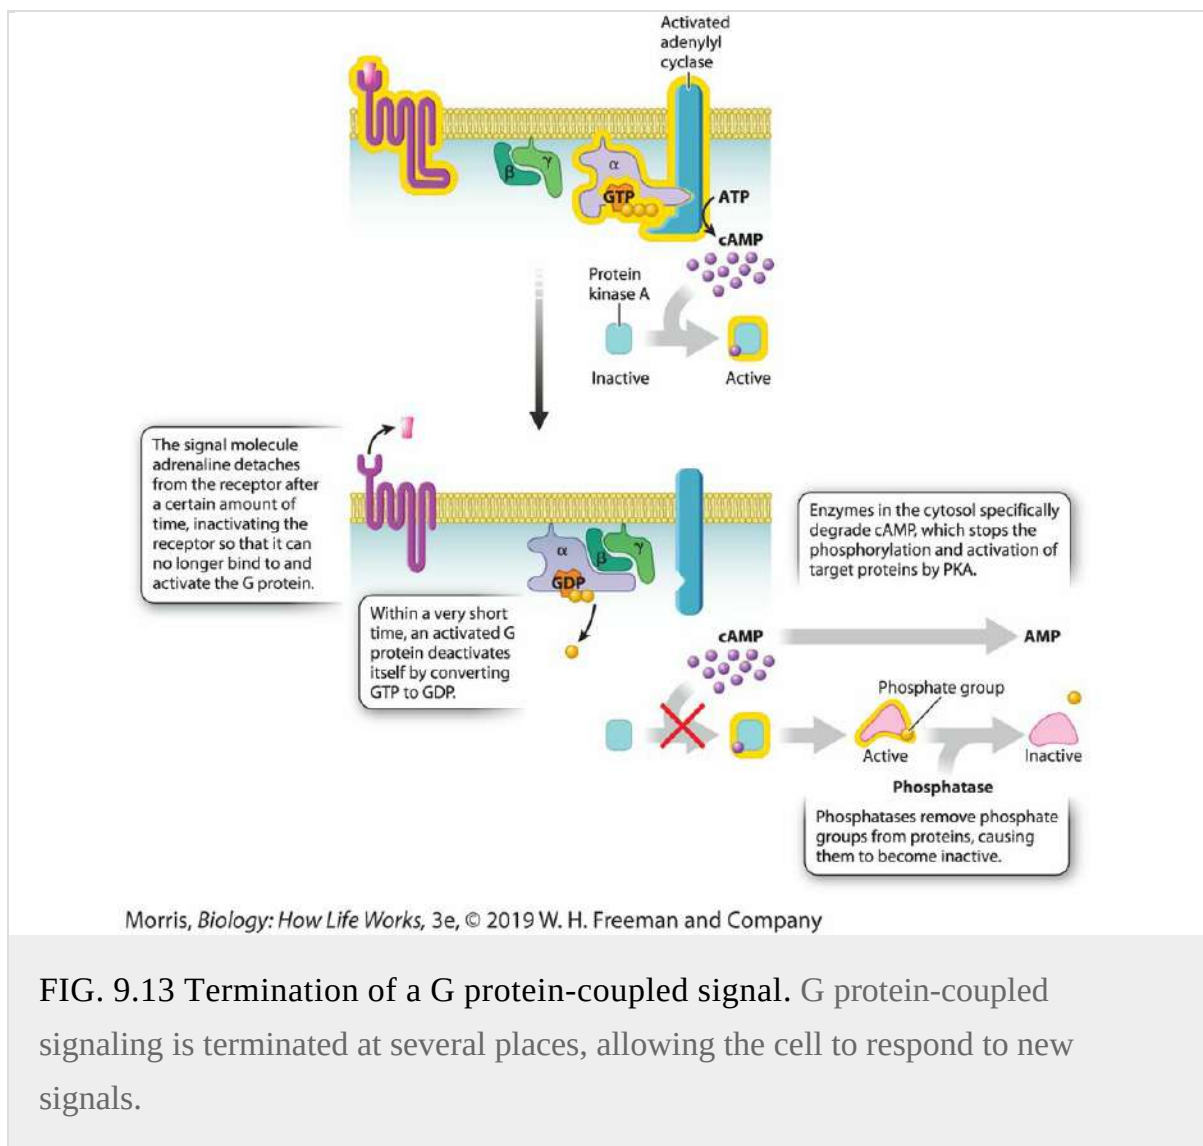

FIG. 9.13 Termination of a G protein-coupled signal. G protein-coupled signaling is terminated at several places, allowing the cell to respond to new signals.

Even when a receptor is turned off, a signal will continue to be transmitted unless the other components of the signaling pathway are

also inactivated. A second place where the signal is terminated is at the G protein ([Fig. 9.13](#)). G proteins can catalyze the hydrolysis of GTP to GDP and inorganic phosphate. This means that an active, GTP-bound  $\alpha$  subunit in the “on” position automatically turns itself “off” by converting GTP to GDP. In fact, the  $\alpha$  subunit converts GTP to GDP almost as soon as a molecule of GTP binds to it. Thus, a G protein is able to activate adenylyl cyclase, and adenylyl cyclase is able to make cAMP only during the very short time it takes the  $\alpha$  subunit to convert GTP to GDP. Without an active receptor to generate more active G protein  $\alpha$  subunits, transmission of the signal quickly comes to a halt.

Farther down the pathway, an enzyme converts the second messenger cAMP to AMP, which no longer activates protein kinase A. Phosphatases remove the phosphate groups added by PKA, inactivating PKA’s target proteins ([Fig. 9.13](#)). In fact, most signaling pathways are counteracted at one or more points as a means of terminating the cell’s response to the signal.

#### Self-Assessment Questions

9. Is the term “G protein” just a shorter name for a G protein-coupled receptor?
10. What are three ways in which a signal is amplified in a G protein-coupled receptor signaling pathway?
11. What are three ways in which the response of a cell to a signal can be terminated?

## 9.5 RECEPTOR KINASES

Like the cells responding to G protein-coupled receptors, cells respond to signaling through receptor kinases in many ways. In response to receptor kinase signaling during embryonic development, limb buds form and eventually elongate into our arms and legs. When we cut a finger, platelets in the blood release platelet-derived growth factor, a receptor kinase ligand that triggers the cell division necessary to repair the wound.

Signaling through receptor kinases takes place in most eukaryotic organisms, and the structure and function of these receptors have been conserved over hundreds of millions of years. A well-studied receptor kinase called Kit provides an example. In vertebrates, signaling through the Kit receptor kinase leads to the production of pigment in skin, feathers, scales, and hair. As you can see from [Fig. 9.14](#), mammals, reptiles, birds, and fish with a mutation in the *kit* gene have similar large white patches with no pigment. This observation indicates that the function of this gene has remained fairly constant since the appearance of the last common ancestor of these groups, more than 500 million years ago. (By convention, the name of a protein, like Kit, is capitalized and in roman type. The name of the gene that encodes the protein, like *kit*, is lowercase and italicized.)

Sources: (clockwise) Mark Boulton/Science Source; Mark Smith/Science Source; CID/ISM/Science Source; Werner Bollmann/Getty Images; Phillip Colla/Oceanlight.

FIG. 9.14 Mutations in the Kit receptor kinase. Similar patterns of incomplete pigmentation are present in mammals, reptiles, birds, and fish that have this mutated receptor.

The cellular responses that result from receptor kinase activation tend to be more long-lasting than the shorter-term changes that result from G protein-coupled receptors. That difference reflects the fact that receptor kinase activation often leads to changes in gene expression that allow cells to grow, divide, differentiate, or change shape.

**Receptor kinases phosphorylate each other, activate intracellular signaling pathways, lead to a response, and are terminated.**

Signaling through receptor kinases follows the same basic sequence of events that we saw in signaling by G protein-coupled receptors, including receptor activation, signal transduction, cellular response,

and termination. Let's consider an example. Think about the last time you got a cut. The cut likely bled for a minute or two, and then the bleeding stopped. The signaling molecule platelet-derived growth factor helps start the healing process. When platelets in the blood encounter damaged tissue, they release a number of proteins, including PDGF. This signaling molecule binds to PDGF-specific receptor kinases on the surface of cells at the site of a wound.

Receptor kinases have an extracellular portion that binds the signaling molecule and an intracellular portion that is a kinase, an enzyme that transfers a phosphate group from ATP to another molecule. A single molecule of PDGF binds to the extracellular portion of two receptors at once, causing the receptors to partner, or dimerize, with each other. As a consequence, the kinase domains of the paired receptors are activated and phosphorylate each other at multiple sites on their tails ([Fig. 9.15](#)). The addition of these phosphate groups provides places on the receptor where other proteins in the cytoplasm can bind and become active.

FIG. 9.15 Receptor kinase activation and signaling. Receptor kinases bind signaling molecules, dimerize, phosphorylate each other, and activate intracellular signal molecules.

One of the downstream targets of an activated receptor kinase is Ras. Ras is a G protein that consists of a single subunit, similar to the  $\alpha$  subunit of the three-subunit G proteins. In the absence of a signal, Ras is bound to GDP and is inactive. However, when Ras is activated by a receptor kinase, it exchanges GDP for GTP. Activated GTP-bound Ras triggers the activation of a protein kinase that is the first in a series of kinases that are activated in turn, as each kinase phosphorylates the next in the series. Collectively, the series of kinases are called the mitogen-activated protein (MAP) kinase pathway ([Fig. 9.16](#)). The final activated kinase in the series enters the nucleus, where it phosphorylates target proteins. Some of these proteins include transcription factors that turn on genes needed for cell division so that your cut can heal.

Morris, *Biology: How Life Works*, 3e, © 2019  
W. H. Freeman and Company

FIG. 9.16 The MAP kinase pathway. Some receptor kinases signal through Ras, which in turn activates the MAP kinase pathway, leading to changes in gene expression.

The signal is amplified many times as it is passed from kinase to kinase. Each phosphorylated kinase in the series activates many molecules of the downstream kinase, and the downstream kinase in turn activates many molecules of another kinase still farther downstream. In this way, a very small amount of signaling molecule (PDGF, in our example) can cause a large-scale response in the cell.

Receptor kinase signaling is terminated by the same basic mechanisms that are involved in G protein-coupled receptor pathways. For example, protein phosphatases inactivate receptor kinases and the enzymes of the MAP kinase pathway. Furthermore, Ras quickly converts GTP to GDP and becomes inactive, just like the G protein  $\alpha$  subunit. Without an active receptor kinase to generate more active Ras, activation of the MAP kinase pathway stops.

## CASE 2 CANCER: CELL SIGNALING, FORM, AND DIVISION

### How do cell signaling errors lead to cancer?

Many cancers arise when something goes wrong with the way a cell responds to a signal for cell division or, in some cases, when a cell behaves as if it has received a signal for cell division when in fact it hasn't. Defects in cell signaling that lead to cancer can take place at just about every step in the cell signaling process.

In some cases, a tumor may form when a signaling molecule is

overproduced or produced in an altered form. In other cases, the source of the problem is the receptor. For example, individuals with some forms of cancer have from 10 to 100 times the normal number of receptors for a signaling molecule called epidermal growth factor (EGF). The EGF receptor is a receptor kinase, like the PDGF receptor. Under normal conditions, binding of EGF to its receptor leads to the controlled division of cells. However, in cancer, the presence of excess receptors heightens the response of the signaling pathway, leading to abnormally high gene expression and excess cell division. In certain breast cancers, for example, an EGF receptor called HER2/neu is overexpressed.

Farther down the pathway, mutant forms of the Ras protein are often present in cancers. One especially harmful mutation prevents Ras from converting its bound GTP to GDP. The protein remains locked in the active GTP-bound state, causing the sustained activation of the MAP kinase pathway. More than 30% of all human cancers involve abnormal Ras activity as a result of one or more mutations in the *ras* gene.

## Signaling pathways are integrated to produce a response in a cell.

In this chapter, we have focused on individual signaling pathways to illustrate the general principles of communication between cells. In each case, we saw that a cell releases a signaling molecule or in some cases retains the signaling molecule attached to its surface. The signaling molecule binds to a cell-surface or intracellular receptor. Binding of the signaling molecule induces a conformational change in

the receptor, causing it to become active. The activated receptor then causes changes in the interior of the cell, frequently turning on a signal transduction cascade that is amplified and leads to a cellular response. Eventually, the response terminates, and the cell is ready to receive new signals.

Focusing on each pathway one at a time allowed us to understand how each pathway operates. But in the context of an entire organism or even a single cell, cell signaling can be quite complex, with multiple pathways acting at once and interacting with one another.

Multiple types of signaling molecules can bind to receptors on a single cell and activate several signaling pathways simultaneously. In this case, a cell's final response depends on how the pathways intersect with one another. The integration of different signals gives cells a wide range of possible responses to their environment. For example, receiving two different signals may enhance a particular response, such as cell growth.

Alternatively, one signal may inhibit the signaling pathway triggered by the other signal, weakening the response. For example, studies have shown that activated PKA can inhibit enzymes in the MAP kinase pathway. Recall that PKA is activated by the G protein-coupled receptor pathway. So, activation of the G protein-coupled pathway can inhibit the receptor kinase pathway.

Researchers have started to make use of this molecular cross talk in studying cancer. For example, many patients with breast cancer have elevated MAP kinase activity in their tumor cells. When human breast

cancer cells are genetically modified to express an activated G protein  $\alpha$  subunit and then transplanted into mice, their growth is significantly reduced. In addition, in cell culture, elevated cAMP levels block cells from responding to growth factors that use the MAP kinase pathway. As we better understand how different signaling pathways interact in specific cell types, we may become able to alter the activity of particular pathways and ultimately the response of the cell.

Self-Assessment Question

12. How are receptor kinase pathways similar to G protein-coupled receptor pathways, and how are they different?

## CORE CONCEPTS SUMMARY

**9.1 PRINCIPLES OF CELL SIGNALING:** Cells communicate primarily by sending and receiving chemical signals.

There are four essential players in communication between two cells: a signaling cell, a signaling molecule, a receptor protein, and a responding cell. [page 186](#)

The signaling molecule binds to its receptor on the responding cell, leading to receptor activation, signal transduction and amplification, a cellular response, and eventually termination of the response. [page 187](#)

**9.2 DISTANCE BETWEEN CELLS:** Cells communicate over long and short distances.

Endocrine signaling takes place over long distances and often relies on the circulatory system for transport of signaling molecules. [page 188](#)

Paracrine signaling takes place over short distances between neighboring cells and relies on diffusion. [page 188](#)

Autocrine signaling occurs when a cell signals itself. [page 189](#)

Some forms of cell communication depend on direct contact between two cells. [page 189](#)

**9.3 SIGNALING RECEPTORS:** Signaling molecules bind to and activate cell-surface and intracellular receptors.

A signaling molecule, or ligand, binds specifically to the ligand-binding site of the receptor. Binding causes the receptor to undergo a conformational change that activates the receptor. [page 191](#)

Receptors for polar signaling molecules, including growth factors, are located on the plasma membrane. [page 191](#)

Receptors for nonpolar signaling molecules, such as steroid hormones, are located in the cytosol or in the nucleus. [page 192](#)

There are three major types of cell-surface receptors: G protein-coupled receptors, receptor kinases, and ion channels. All act as molecular switches. [page 192](#)

G protein-coupled receptors associate with G proteins, which relay the signal to the interior of the cell. [page 192](#)

Receptor kinases activate target proteins. [page 192](#)

Ligand-gated ion channels open in response to a signal, allowing the movement of ions across the plasma membrane. [page 193](#)

**9.4 G PROTEIN-COUPLED RECEPTORS:** G protein-coupled receptors are a large, conserved family of receptors that often lead to short-term responses, such as activating enzymes or opening ion channels.

G protein-coupled receptors bound to signaling molecules associate with G proteins. [page 193](#)

G proteins are active when bound to GTP and inactive when bound to GDP. [page 193](#)

Some G proteins are composed of three subunits, denoted  $\alpha$ ,  $\beta$ , and  $\gamma$ . When a G protein encounters an activated receptor, the  $\alpha$  subunit exchanges GDP for GTP, dissociates from the  $\beta$  and  $\gamma$  subunits, and becomes active. [page 194](#)

The GTP-bound  $\alpha$  subunit activates adenylyl cyclase, which converts ATP into the second messenger cAMP. [page 194](#)

Signal transduction cascades are amplified in the cytosol. [page 194](#)

Cellular responses to G protein-coupled receptor signals tend to be short-lived and are quickly terminated. [page 195](#)

**9.5 RECEPTOR KINASES:** Receptor kinases are widespread and often lead to long-term responses, such as changes in gene expression.

Ligand binding to receptor kinases causes them to dimerize. The paired receptor kinases phosphorylate each other's cytoplasmic domains, leading to activation of intracellular signaling pathways. [page 198](#)

The phosphorylated receptors bind other proteins, which in turn activate other cytosolic signaling molecules, such as Ras. [page 198](#)

When Ras is activated, the GDP to which it is bound is released and is replaced by GTP. The active, GTP-bound Ras binds to and activates the first in a series of kinases. [page 198](#)

Cancer can be caused by errors in any step of the signaling pathways involved in cell division. [page 198](#)

Mutations in receptor kinases and Ras are frequently associated

with human cancers. [page 199](#)

Several signaling pathways can take place simultaneously in a single cell, and the cellular response depends on how these pathways interact. [page 199](#)

# CHAPTER 10 Cell and Tissue Architecture

## Cytoskeleton, Cell Junctions, and Extracellular Matrix

F. Fox/AGE Fotostock

### CORE CONCEPTS

**10.1 TISSUES AND ORGANS:** Tissues and organs are communities of cells that perform specific functions.

**10.2 THE CYTOSKELETON:** The cytoskeleton is composed of microtubules, microfilaments, and intermediate filaments that help maintain cell shape.

**10.3 CELL JUNCTIONS:** Cell junctions connect cells to one another to form tissues.

**10.4 THE EXTRACELLULAR MATRIX:** The extracellular matrix provides structural support and informational cues.

---

A recurring theme in this book, and in all of biology, is that form and function are inseparably linked. This is true at every level of structural organization, from molecules to organelles to cells and to organisms themselves. We saw in [Chapter 4](#) that the function of proteins depends on their shape. In [Chapters 7](#) and [8](#), we saw that the function of organelles like mitochondria and chloroplasts depends in part on the large surface areas of internal membranes.

The functions of different cell types are also reflected in their shape and internal structural features ([Fig. 10.1](#)). Consider a red blood cell. It is shaped like a disk that is slightly indented in the middle, and it lacks a nucleus and other organelles ([Fig. 10.1a](#)). This unusual shape and internal organization allow it to deform readily, so it can pass through blood vessels with diameters smaller than that of the red blood cell itself. Spherical cells in the liver ([Fig. 10.1b](#)) that synthesize proteins and glycogen look and function very differently from the long, slender muscle cells ([Fig. 10.1c](#)) that contract to exert force. A neuron ([Fig. 10.1d](#)), has long and extensively branched extensions that communicate with other cells. It is structurally and functionally quite

distinct from a cell lining the intestine ([Fig. 10.1e](#)) that absorbs nutrients.

The biconcave shape of a red blood cell maximizes its surface area for gas exchange and allows it to deform as it passes through the circulatory system.

Hepatocytes (liver cells) contain large amounts of rough ER, shown here surrounding the central nucleus, needed for protein synthesis.

Long, multinucleated muscle cells have a striped appearance and are specialized for contraction.

Long, slender extensions of the plasma membrane allow neurons to communicate with other cells.

Thin, comb-like projections, called microvilli, on intestinal cells increase their absorptive surface area.

FIG. 10.1 Diverse cell types. Cells differ in shape and are well adapted for their various functions.

In multicellular organisms, cells often exist in communities, forming tissues and organs. Again, form and function are intimately linked. Think of the branching structure and large surface area of the mammalian lung, which is adapted for gas exchange, or the muscular heart, which is adapted for pumping blood through large circulatory systems.

In this chapter, we look at the internal structures of cells that determine their shapes. We also examine the different ways cells connect to one another to build tissues and organs. Finally, we discuss the physical environment outside cells that is synthesized by cells and influences their behavior.

# 10.1 TISSUES AND ORGANS

Multicellular organisms consist of communities of cells with several notable features (discussed both in this section and in [Chapter 26](#)).

First, cells adhere to one another. Most cells in multicellular organisms are physically attached to other cells or to substances in their surroundings. Second, cells communicate with one another. As we saw in [Chapter 9](#), cells respond to signals from neighboring cells and the physical environment. In addition, as we will see, cells in tissues have pathways for the movement of molecules from one cell to another. Third, cells are specialized to carry out different functions as a result of their development and differentiation. The different shapes of cells often reflect these specialized functions.

## Tissues and organs are communities of cells.

A biological [tissue](#) is a collection of cells that work together to perform a specific function. Animals and plants have tissues that allow them to carry out the various processes necessary to sustain them. In animals, for example, four types of tissues—epithelial, connective, nervous, and muscle—combine to make up all the organs of the body ([Chapter 33](#)). Two or more tissues often combine and function together as an [organ](#), such as a heart or lung.

Tissues and organs have distinctive shapes that reflect how they work and what they do. In the same way, the different cell types that make up these organs have distinctive shapes that reflect what they do in the organ. In animals, the shape of cells is determined and

maintained by structural protein networks in the cytoplasm called the **cytoskeleton** ([section 10.2](#)). The shape and structural integrity of tissues and organs depend on the ability of cells to connect to one another. In turn, the connection of cells to one another depends on structures called **cell junctions** ([section 10.3](#)). Outside many cells and tissues is a meshwork of proteins and polysaccharides called the **extracellular matrix** ([section 10.4](#)). The ability of cells to adhere to this meshwork is important to ensure a strong, properly shaped tissue or organ.

## The structure of skin relates to its function.

To understand the role of the cytoskeleton, cell junctions, and the extracellular matrix, let's consider a community of cells very familiar to all of us—our own skin ([Fig. 10.2](#)). The structure of mammalian skin is tied to its function. Skin has two main layers. The outer layer, the **epidermis**, serves as a water-resistant, protective barrier. The inner layer, the **dermis**, supports the epidermis, both physically and by supplying it with nutrients. It also provides a cushion surrounding the body.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Photo source: Jose Luis Pelaez Inc/Getty Images.

FIG. 10.2 The skin. The skin is a community of cells organized into two layers, the epidermis and the dermis. Together these layers provide protection for the underlying tissues of the body.

As you can see in [Fig. 10.2](#), the epidermis is several cell layers thick. Cells arranged in one or more layers are called epithelial cells and together make up a type of animal tissue called epithelial tissue. Epithelial tissue covers the outside of the body and lines many internal structures, such as the digestive tract and vertebrate blood vessels. The epidermal layer of skin is primarily composed of epithelial cells called

keratinocytes. The epidermis also contains melanocytes, which produce the pigment that gives skin its color.

Keratinocytes in the epidermis are specialized to protect the underlying tissues and organs. They are able to perform this function in part because of their elaborate system of cytoskeletal filaments. These filaments are often connected to the cell junctions that hold adjacent keratinocytes together. Cell junctions also connect the bottom layer of keratinocytes to a specialized form of extracellular matrix called the **basal lamina** (also called the basement membrane, although it is not really a membrane). The basal lamina underlies and supports all epithelial tissues.

The dermis is made up mostly of connective tissue, a type of tissue characterized by few cells and substantial amounts of extracellular matrix. The main type of cell in the dermis is the fibroblast, which synthesizes the extracellular matrix. The dermis is strong and flexible because its extracellular matrix is composed of tough protein fibers. The dermis also contains many blood vessels and nerve endings.

We will come back to the skin several times in this chapter to show more precisely how these multiple connections among cytoskeleton, cell junctions, and the extracellular matrix make the skin a watertight and strong protective barrier.

#### Self-Assessment Questions

1. What are the four basic tissue types in animals?
2. How does the structure of the epidermis of the skin relate to its

function?

## 10.2 THE CYTOSKELETON

Just as the bones of vertebrate skeletons provide internal support for the body, the protein fibers of the cytoskeleton provide internal support for cells (**Fig. 10.3**). All eukaryotic cells have at least two cytoskeletal elements, **microtubules** and **microfilaments**. Animal cells also have a third element, **intermediate filaments**. All three of these cytoskeletal elements are long chains, or polymers, made up of protein subunits. In addition to providing structural support, microtubules and microfilaments enable cells to change shape, move about, and transport substances.

**Microtubules and microfilaments are polymers of protein subunits.**

Microtubules are hollow tubelike structures with the largest diameter

of the three cytoskeletal elements, about 25 nm ([Fig. 10.3a](#)). They are polymers of protein dimers. Each dimer is made up of two slightly different [tubulin](#) proteins, called  $\alpha$  (alpha) and  $\beta$  (beta) tubulin. The tubulin dimers are assembled to form the microtubule.

Microtubules help maintain cell shape and internal structure. In animal cells, these structures radiate outward to the cell periphery from a microtubule organizing center called the [centrosome](#). This spokelike arrangement of microtubules helps cells withstand compression. Many organelles are tethered to microtubules, so that microtubules guide the arrangement of organelles in the cell.

Microfilaments are polymers of [actin](#) monomers, arranged to form a helix. The thinnest of the three cytoskeletal fibers, they are approximately 7 nm in diameter. Microfilaments are present in various locations in the cytoplasm ([Fig. 10.3b](#)). They are relatively short and extensively branched in the cell cortex, the area of the cytoplasm just beneath the plasma membrane. In the cortex, microfilaments reinforce the plasma membrane and help to organize proteins associated with it.

These cortical microfilaments also play important roles in maintaining the shape of a cell, such as the biconcave shape of red blood cells discussed earlier (see [Fig. 10.1a](#)). In addition, long bundles of microfilaments form a band that extends around the circumference of epithelial cells. Microfilaments also maintain the shape of absorptive epithelial cells such as those in the small intestine. In these cells, bundles of microfilaments are found in microvilli, hairlike projections that extend from the surface of the cell ([Fig. 10.4](#)).

## Microtubules and microfilaments are dynamic structures.

When we think of the parts of a skeleton, we are inclined to think of our bones. Unlike our bones, which undergo remodeling but do not change rapidly, microtubules and microfilaments are dynamic. They become longer by adding subunits to their ends, and become shorter by losing subunits.

The rate at which protein subunits are added depends on the concentrations of tubulin and actin in that region of the cell. When high concentrations of subunits are present, microtubules and microfilaments can become longer at both ends, although the subunits are assembled more quickly on one end than on the other. The faster-

assembling end is called the plus end, and the slower-assembling end is called the minus end ([Fig. 10.5](#)).

The ability of microfilaments and microtubules to lengthen and shorten is important for some of their functions. For example, some forms of cell movement, such as a single-celled amoeba foraging for food or a mammalian white blood cell chasing down foreign bacteria, depend on actin polymerization and depolymerization. The lengthening/shortening ability is also required when a single cell divides in two during cytokinesis ([Chapter 11](#)).

Microtubules make up the spindles that attach to chromosomes during cell division. In this case, the ability of spindle microtubules to “explore” the space of the cell and encounter chromosomes is driven by a unique property of microtubules: their plus ends undergo seemingly random cycles of rapid depolymerization followed by slower polymerization. These cycles of depolymerization and polymerization, which are called **dynamic instability** ([Fig. 10.6](#)), allow spindle microtubules to quickly find and attach to chromosomes during cell division.

## Motor proteins associate with microtubules and microfilaments to cause movement.

As noted earlier, microtubules and microfilaments have some capacity to lengthen and shorten by polymerization and depolymerization.

When joined by small accessory proteins called [motor proteins](#), microtubules and microfilaments are capable of causing amazing movements. A motor is a device that imparts motion.

For example, microtubules function as tracks for transport within the cell. Two motor proteins that associate with these microtubule tracks are [kinesin](#) and [dynein](#). Kinesin transports cargo toward the plus end of microtubules, located at the periphery of the cell ([Fig. 10.7](#)). By contrast, dynein carries its load away from the plasma membrane toward the minus end, located at the centrosome in the interior of the cell. Movement along microtubules by kinesin and dynein is driven by conformational changes in the motor proteins and is powered by energy harvested from ATP.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 10.7 Intracellular transport. The motor protein kinesin interacts with microtubules to move vesicles in the cell.

Let's look at an especially striking example of this system at work. Specialized skin cells called melanophores are present in some vertebrates. Melanophores are similar to the melanocytes in our own skin that produce the pigment melanin. However, rather than hand off their melanin to other cells (as occurs in humans), melanophores keep their pigment granules and move them around inside the cell in response to hormones or neuronal signals. This redistribution of melanin within the cell allows animals such as fish or amphibians to change color. For example, at night the melanin granules in the skin of a zebrafish embryo are dispersed throughout the melanophores, making the skin darkly colored. As morning comes and the day brightens, the pigment granules aggregate at the center of the cell around the centrosome, causing the embryo's color to lighten ([Fig. 10.8](#)).

FIG. 10.8 Color change in zebrafish embryos driven by motor proteins kinesin and dynein. Melanin granules are redistributed along microtubules in the melanophores of the skin.

The melanin granules in the melanophores move back and forth

along microtubules, transported by kinesin and dynein. Kinesin moves the granules out toward the plus end of the microtubule during dispersal, and dynein moves them back toward the minus end during aggregation. The color change provides daytime and nighttime camouflage: hungry predators lurking in the water below are less likely to spot the young, developing zebrafish embryo.

In addition to providing tracks for the transport of material within the cell, microtubules are found in [cilia](#) (singular cilium). Cilia are rod-like structures that extend from the surface of cells and are well conserved across eukaryotes. There are two types of cilia: those that don't move (called nonmotile cilia) and those that move (called motile cilia). Nonmotile cilia are very common and can be found on many eukaryotic cells. In these cells, they often serve a sensory function, taking in environmental signals and transducing them to the cell interior. For example, nonmotile cilia are found in mammalian olfactory neurons in the nose and photoreceptors in the eyes.

Motile cilia propel the movement of cells or fluid surrounding the cell ([Fig. 10.9](#)). They can be found in single-celled eukaryotes, such as the green alga *Chlamydomonas* ([Fig. 10.9a](#)) and the protist *Paramecium* ([Fig. 10.9b](#)), where they propel the organisms through the water. They are also found in sperm cells ([Fig. 10.9c](#)). Long, elaborate cilia present in *Chlamydomonas* and sperm cells are sometimes called flagella, but they are similar in structure to the shorter cilia and are unrelated to the flagella found on bacterial cells, so most biologists now prefer the term “cilia.”

**FIG. 10.9 Motile cilia.** Motile cilia move cells or allow cells to propel substances. (a) The green alga *Chlamydomonas* moves by the motion of two long cilia; (b) the protist *Paramecium* is covered with short cilia that beat in a coordinated fashion, allowing the organism to move through its environment; (c) sperm cells swim by movement of one long cilium, which is sometimes called a flagellum; (d) epithelial cells lining the upper respiratory tract have cilia that sweep fluid with debris and pathogens out of the airway.

Motile cilia are also present on epithelial cells, such as those that line the upper respiratory tract ([Fig. 10.9d](#)). These cilia move the fluid above the surface of the cell layer, carrying away foreign particles and pathogens. In motile cilia, microtubules associate with the motor protein dynein. Because the microtubules are fixed in place, dynein causes the microtubules to bend, causing a wave-like motion of the cilia. In turn, the motion of the cilia leads to movement of the cell or surrounding fluid.

Like microtubules, microfilaments associate with motor proteins to produce movement. Actin microfilaments associate with the motor protein [myosin](#) to transport various types of cellular cargo, such as vesicles, within cells. Microfilaments associated with myosin are also responsible for changes in the shape of many types of cell. One of the most dramatic examples of cell shape change is the shortening

(contraction) of a muscle cell. Muscle contraction depends on the interaction of myosin with microfilaments, and is powered by ATP ([Chapter 35](#)).

## Intermediate filaments are polymers of proteins that vary according to cell type.

The intermediate filaments of animal cells have a diameter that is intermediate between those of microtubules and microfilaments, approximately 10 nm (see [Fig. 10.3c](#)). They are polymers of intermediate filament proteins that combine to form strong, cable-like structures in the cell. In this way, they provide cells with mechanical strength.

We have seen that different cell types use tubulin dimers to form microtubules and actin monomers to form microfilaments. By contrast, the proteins making up intermediate filaments differ from one cell type to another. For example, in epithelial cells, these protein subunits are keratins; in fibroblasts, they are vimentins; and in neurons, they are neurofilaments. Some intermediate filaments, called lamins, are even found inside the nucleus, where they provide support for the nuclear envelope ([Fig. 10.10](#)). More than 100 different kinds of intermediate filaments have been identified to date.

Once assembled, many intermediate filaments become attached to cell junctions at their cytoplasmic side, providing strong support for the cells ([Fig. 10.11](#)). In the case of epithelial cells, this anchoring results in structural continuity from one cell to another that greatly strengthens the entire epithelial tissue. This is especially important for tissues that are regularly subject to physical stress, such as the skin and the lining of the intestine.

FIG. 10.11 Intermediate filaments in the epidermis of the skin. Intermediate filaments bind to cell junctions called desmosomes, forming a strong, interconnected network. Epidermolysis bullosa is a group of blistering diseases of the skin that can be caused by a defect in intermediate filaments.

Genetic defects that disrupt the intermediate filament network can have severe consequences. For example, some individuals with epidermolysis bullosa, a group of rare genetic diseases, have defective keratin genes. Intermediate filaments do not polymerize properly in these individuals, so they form weaker connections between the layers of cells that make up the epidermis. As a consequence, the outer layers can detach, resulting in extremely fragile skin that blisters in response to the slightest trauma ([Fig. 10.11](#)). The sensitivity to physical stress is so extreme that infants with epidermolysis bullosa often suffer significant damage to the skin during childbirth. Therefore, cesarean

section is sometimes recommended in cases where the disease is diagnosed during pregnancy.

## The cytoskeleton is an ancient feature of cells.

Actin and tubulin are found in all eukaryotic cells, and their structure and function have remained relatively unchanged throughout the course of evolution. The amino acid sequences of yeast tubulin and human tubulin are 75% identical. In fact, a mixture of yeast and human actin monomers forms hybrid microfilaments that are able to function normally in the cell.

Not long ago, it was believed that cytoskeletal proteins were present only in eukaryotic cells. Recently, a number of studies have shown that many prokaryotes also have a system of proteins similar in structure to the cytoskeletal elements of eukaryotic cells. These bacterial proteins are involved in similar processes as those in eukaryotic cells, including the separation of daughter cells during cell division. Interestingly, at least one of these prokaryotic cytoskeleton-like proteins is expressed in the mitochondria and chloroplasts of some eukaryotic cells. The presence of this protein in these organelles lends support to the theory that mitochondria and chloroplasts were once independent prokaryotic cells that developed a symbiotic relationship with another cell. This idea, called the endosymbiotic theory, is discussed in [Chapter 25](#).

The subunits and major functions of microtubules, microfilaments, and intermediate filaments are summarized in [Table 10.1](#).

**TABLE 10.1 Major Functions of Cytoskeletal Elements**

**TABLE 10.1 Major Functions of Cytoskeletal Elements**

| CYTOSKELETAL ELEMENT   | SUBUNITS       | MAJOR FUNCTIONS                                                                                                                                                             |

### Self-Assessment Questions

3. What are three types of cytoskeletal elements? For each, indicate the subunits they are composed of, their relative size, and major functions.
4. How is the dynamic nature of microtubules and microfilaments important for their functions?
5. What are three types of motor proteins? For each, indicate which

cytoskeletal element it interacts with and its function.

6. Would a defect in dynein or in kinesin cause a zebrafish embryo to remain darkly colored after daybreak?

## 10.3 CELL JUNCTIONS

The cell is the fundamental unit of living organisms ([Chapter 1](#)). Recent estimates place the number of cells in an adult human at approximately 30–40 trillion. Although it is difficult to determine this number exactly, it is clear that humans, as well as other multicellular organisms, are made up of a lot of cells! But what keeps us from slumping into a pile of cells? And what keeps cells organized into tissues, and tissues into organs?

Tissues are held together and function as a unit because of cell junctions. Cell junctions physically connect one cell to the next and anchor cells to the extracellular matrix. Some tissues have cell junctions that perform roles other than adhesion. For example, cell junctions in the outer layer of the skin and the lining of intestine provide a seal so that the epithelial sheet can act as a selective barrier. Other cell junctions allow adjacent cells to communicate so that they work together as a unit. In this section, we look more closely at the roles of the various types of cell junctions in tissues, as well as their interactions with the cytoskeleton.

### Cell adhesion molecules allow cells to attach to other cells and to the extracellular matrix.

In 1907, American embryologist H. V. Wilson discovered that if he pressed a live sponge through fine cloth, he could break up the sponge into individual cells. If he then swirled the cells together, they would coalesce back into a group resembling a sponge. If he swirled the cells

from sponges of two different species together, the cells sorted themselves out—that is, cells from one species of sponge associated only with cells from that same species ([Fig. 10.12a](#)). Fifty years later, German-born embryologist Johannes Holtfreter took neuronal cells and skin cells from an amphibian embryo and treated them the same way that Wilson had treated sponge cells. He observed that the embryonic cells sorted themselves according to tissue type ([Fig. 10.12b](#)).

FIG. 10.12 Cell type–specific cell adhesion. Experiments showed that cells from (a) sponges and from (b) amphibian embryos are in each case able to adhere to one another in a specific manner.

Cells are able to sort themselves because proteins on the surfaces of

cells of the same type recognize each other. Various proteins on the cell surface called [cell adhesion molecules](#) attach cells to one another or to the extracellular matrix. While a number of cell adhesion molecules are now known, the [cadherins](#) (calcium-dependent adherence proteins) are especially important. Many different kinds of cadherins exist, but a given cadherin may bind only to another cadherin of the same type. This property explains Holtfreter's observations that cells from amphibian embryos sorted themselves by tissue type. E-cadherin ("epidermal cadherin") is present on the surface of embryonic epidermal cells, and N-cadherin ("neural cadherin") is present on neuronal cells. The epidermal cells adhere to one another through E-cadherin, and the neuronal cells adhere to one another through N-cadherin.

Cadherins are transmembrane proteins ([Chapter 5](#)). The extracellular domain of a cadherin molecule binds to the extracellular domain of a cadherin of the same type on an adjacent cell. The cytoplasmic portion of the protein is linked to the cytoskeleton, including microfilaments and intermediate filaments ([Fig. 10.13a](#)). This arrangement essentially connects the cytoskeleton of one cell to the cytoskeleton of another, increasing the strength of tissues and organs.

As well as being stably connected to other cells, cells attach to proteins of the extracellular matrix through cell adhesion molecules called **integrins**. Like cadherins, integrins are transmembrane proteins, and their cytoplasmic domain is linked to microfilaments or intermediate filaments (**Fig. 10.13b**). Also like cadherins, integrins are of many different types, each binding to a specific extracellular matrix protein. Integrins are present on the surface of virtually every animal cell. In addition to their role in adhesion, integrins act as receptors that communicate information about the extracellular matrix to the interior of the cell (**section 10.4**).

**Anchoring junctions connect adjacent cells and are reinforced by the**

# cytoskeleton.

Cadherins and integrins are often organized into cell junctions, complex structures in the plasma membrane that allow cells to adhere to one another. These anchoring cell junctions are of two types: adherens junctions and desmosomes ([Fig. 10.14](#)).

FIG. 10.14 Cell junctions. Cell junctions connect cells to other cells or to the basal lamina. They are reinforced by the cytoskeleton.

In [section 10.2](#), we saw that a long bundle of actin microfilaments forms a band that extends around the circumference of epithelial cells, such as those lining the intestine. This band of actin is attached to the plasma membrane by cadherins in a beltlike structure called an [adherens junction](#) ([Fig. 10.14](#)). The cadherins in the adherens junction of one cell attach to the cadherins in the adherens junctions of adjacent cells. This arrangement establishes a physical connection among the actin cytoskeletons of all cells present in an epithelial layer.

Like adherens junctions, [desmosomes](#) are cell junctions that allow cells to adhere to one another. Whereas adherens junctions form a belt around the circumference of cells, desmosomes are buttonlike points of adhesion ([Fig. 10.14](#)). Cadherins are at work here, too, strengthening the connection between cells. Cadherins in the desmosome of one cell bind to cadherins in the desmosomes of adjacent cells. The cytoplasmic domain of these cadherins connects to intermediate filaments in the cytoskeleton. This second type of physical connection among neighboring cells greatly enhances the strength of epithelial cell layers.

Epithelial cells are attached not only to one another, but also to the underlying extracellular matrix (specifically, the basal lamina). In this case, the cells are firmly anchored to the extracellular matrix by a type of desmosome called a [hemidesmosome](#) ([Fig. 10.14](#)). Integrins are the most prominent cell adhesion molecules in hemidesmosomes. The extracellular domains bind extracellular matrix proteins, and the

cytoplasmic domains connect to intermediate filaments. These intermediate filaments connect to desmosomes in other parts of the plasma membrane. The result is a firmly anchored and reinforced layer of cells.

## Tight junctions prevent the movement of substances through the space between cells.

Epithelial cells form sheets or boundaries that line tissues and organs, including the digestive tract, respiratory tract, and outer layer of the skin. Like any effective boundary, a layer of epithelial cells must limit or control the passage of material across it. Adherens junctions and desmosomes provide strong adhesion between cells, but they do not prevent materials from passing freely through the spaces between the cells. This function is provided by a different type of cell junction. In vertebrates, these are called **tight junctions** ([Fig. 10.14](#)). Tight junctions establish a seal between cells that prevents molecules from moving through this channel. For example, the only way a substance can travel from one side of a sheet of epithelial cells to the other is by moving *through* the cells by means of one of the cellular transport mechanisms discussed in [Chapter 5](#).

A tight junction is a band of interconnected strands of integral membrane proteins, particularly proteins called claudins and occludins. Like adherens junctions, tight junctions encircle the epithelial cell. The proteins forming the tight junction in one cell bind to the proteins forming the tight junctions in adjacent cells. Also like adherens

junctions, tight junctions connect to actin microfilaments.

The tight junction divides the plasma membrane into two distinct regions ([Fig. 10.14](#)). Thus cells that have tight junctions have two sides. The portion of the plasma membrane in contact with the lumen, or the inside of any tubelike structure such as the gut, is called the apical membrane. The apical membrane defines the “top” side of the cell. The rest of the plasma membrane is the basolateral membrane, which defines the bottom (“baso”) and sides (“lateral”) of the cell.

A tight junction prevents lipids and proteins in the membrane on one side of the junction from diffusing to the other side. As a result, the apical and basolateral membranes of a cell are likely to have different integral membrane proteins, which causes them to be functionally different as well. In the small intestine, for example, glucose is transported from the lumen into intestinal epithelial cells by transport proteins on the apical side of the cells, and is transported out of the cells into the circulation by facilitated diffusion through a different type of glucose transporter restricted to the basolateral sides of the cells ([Chapter 38](#)).

## Molecules pass between cells through communicating junctions.

Not all cell junctions are involved in the adhesion of cells to each other or in sealing a layer of cells. [Gap junctions](#) ([Fig. 10.14](#)) of animal cells and [plasmodesmata](#) of plant cells (see [Fig. 5.17b](#)) permit materials to pass directly from the cytoplasm of one cell to the cytoplasm of another, allowing cells to communicate with one another.

Gap junctions are a complex of integral membrane proteins called connexins arranged in a ring. The ring of connexin proteins connects to a similar ring of proteins in the membrane of an adjacent cell. Together, the two connexin rings form a channel that connects the cytoplasm of adjacent cells. Ions and signaling molecules pass through these junctions, allowing cells to act in unison. In the heart, for example, ions pass through gap junctions connecting cardiac muscle cells. This rapid electrical communication allows the muscle cells to beat in a coordinated fashion ([Chapter 37](#)).

Plasmodesmata (the singular form is “plasmodesma”) are passages through the cell walls of adjacent plant cells. Like gap junctions, they allow cells to exchange ions and small molecules, but the similarity ends there. In plasmodesmata, the plasma membranes of the two connected cells are actually continuous. The size of the opening is considerably larger than that in gap junctions, large enough for cells to transfer RNA molecules and proteins, an ability that is especially important during embryonic development. Plant cells can send signals to one another through plasmodesmata despite being enclosed within rigid cell walls.

In summary, cell junctions interact to create stable communities of cells in the form of tissues and organs. These cell junctions are important for the functions of tissues, allowing cells to adhere to each other and the extracellular matrix, act as a barrier, and communicate rapidly. The types and functions of the cell junctions are summarized in [Table 10.2](#).

**TABLE 10.2** Types and Functions of Cell Junctions

---

| CELL JUNCTION        | MAJOR COMPONENT     | CYTOSKELETAL ATTACHMENT | PRIMARY FUNCTION                   |
|----------------------|---------------------|-------------------------|------------------------------------|
| <b>Anchoring</b>     |                     |                         |                                    |
| Adherens junction    | Cadherins           | Microfilaments          | Cell–cell adhesion                 |
| Desmosome            | Cadherins           | Intermediate filaments  | Cell–cell adhesion                 |
| Hemidesmosome        | Integrins           | Intermediate filaments  | Cell–extracellular matrix adhesion |
| <b>Barrier</b>       |                     |                         |                                    |
| Tight junction       | Claudins, occludins |                         | Epithelial boundary                |
| <b>Communicating</b> |                     |                         |                                    |
| Gap junction         | Connexins           |                         | Communication between animal cells |
| Plasmodesma          | Cell membrane       |                         | Communication between plant cells  |

### Self-Assessment Questions

7. What are three major types and functions of cell junctions?
8. Adherens junctions and desmosomes both attach cells to other cells and are made up of cadherins. How, then, are they different?
9. What do you think would happen if you interfered with the function of cadherins and integrins?

## 10.4 THE EXTRACELLULAR MATRIX

Up to this point, we have looked at how the cytoskeleton maintains the shape of cells. We have also seen how the stable association of animal cells with one another and with the extracellular matrix is made possible by cell junctions, and noted that these junctions are reinforced by the cytoskeleton. As important as the cytoskeleton and cell junctions are to the structure of cells and tissues, it is the extracellular matrix that provides the molecular framework that helps determine the structural architecture of plants and animals.

The extracellular matrix is an insoluble meshwork composed of proteins and polysaccharides. Its components are synthesized, secreted, and modified by many different cell types. The many different forms of extracellular matrix differ in the amount, type, and organization of the proteins and polysaccharides that make them up. In both plants and animals, the extracellular matrix not only contributes structural support, but also provides informational cues that determine the activity of the cells that are in contact with it.

### The extracellular matrix of plants is the cell wall.

The paper we write on, the cotton fibers in the clothes we wear, and the wood in the chairs we sit on are all composed of the extracellular matrix of plants. In plants, the extracellular matrix forms the cell wall, and the main component of the plant cell wall is the polysaccharide cellulose ([Chapters 2](#) and [5](#)). Cellulose is, in fact, the most widespread

organic macromolecule on Earth.

The plant cell wall is possibly one of the most complex examples of an extracellular matrix, and certainly one of the most diverse in terms of the functions it performs. Cell walls maintain the shape and turgor pressure of plant cells and act as a barrier that prevents foreign materials and pathogens from reaching the plasma membrane. In many plants, cell walls collectively serve as a support structure for the entire plant, much like the skeleton of an animal.

The plant cell wall is composed of as many as three layers: the outermost middle lamella, the primary cell wall, and the secondary cell wall, located closest to the plasma membrane ([Fig. 10.15](#)). The middle lamella is synthesized first, during the late stages of cell division. It is composed of a gluelike complex carbohydrate, and is the main mechanism by which plant cells adhere to one another. The primary cell wall is formed next. It consists mainly of cellulose, but also contains a number of other molecules, including pectin. The primary cell wall is laid down while the cells are still growing. It is assembled by enzymes on the surface of the cell and remains thin and flexible.

FIG. 10.15 The three layers of the plant cell wall: middle lamella, primary cell wall, and secondary cell wall. The major component of the plant cell wall is cellulose, a polymer of glucose.

When cell growth has stopped, the secondary cell wall is constructed in many, but not all, plant cells. It is made largely of cellulose, but also contains a substance called lignin. Lignin hardens the cell wall and makes it water resistant. In woody plants, the cell wall can be as much as 25% lignin. The rigid secondary cell wall permits woody plants to grow to tremendous heights. Giant sequoia trees, for example, grow to more than 300 feet, supported entirely by the lignin-reinforced cellulose fibers of the interconnected cell walls.

As a plant cell grows, it must synthesize additional cell wall components to expand the area of the wall. Unlike the extracellular matrix components that are secreted by animal cells, the cellulose polymer is assembled outside the cell, on the extracellular surface of

the plasma membrane. Both the glucose monomers that form the polymer and the enzymes that attach them are delivered to the cell surface by arrays of microtubules. This is yet another example of how the cytoskeleton plays an indispensable role in regulating the shape of a cell.

## The extracellular matrix is abundant in connective tissues of animals.

The extracellular matrix of animals, like that of plants, is a mixture of proteins and polysaccharides secreted by cells. The animal extracellular matrix is composed of large fibrous proteins, including collagen, elastin, and laminin, which impart tremendous tensile strength. These fibrous proteins are embedded in a gel-like polysaccharide matrix. The matrix is negatively charged, attracting positively charged ions and water molecules that provide protection against compression and other physical stress.

The extracellular matrix can be found in abundance in animal connective tissue ([Fig. 10.16](#)). Connective tissue has two functions, both of which are necessary for multicellularity. First, it physically connects various parts of the body. For example, the tendons that connect your muscles to bones and the ligaments that connect your bones to other bones are connective tissue. Second, connective tissue supports various parts of the body. It underlies all epithelial tissues, as we have seen ([section 10.1](#)). For example, the dermis of the skin is a connective tissue that provides support and nutrients to the overlying epidermis. The main type of cell in the dermis is the fibroblast, which synthesizes most of the extracellular matrix proteins.

FIG. 10.16 Animal connective tissue. Connective tissue is composed of protein fibers in a gel-like polysaccharide matrix.

Connective tissue is an unusual tissue type in that it is dominated by the extracellular matrix and has a low cell density. Consequently, the extracellular matrix determines the properties of different types of

connective tissue.

All animals express similar connective tissue proteins, highlighting those proteins' importance and evolutionarily conserved function. Collagen is the most abundant protein in the extracellular matrix of animals. More than 20 different forms of collagen exist, and in humans collagen accounts for almost 25% of all protein present in the body. More than 90% of this collagen is type I collagen. Present in the dermis of the skin, type I collagen provides strong, durable support for the overlying epidermis. Tendons and ligaments are able to withstand the physical stress placed on them because they are made up primarily of collagen.

Collagen's strength is related to its structure. Like a rope or a cable, this protein is composed of intertwined fibers that make it much stronger than if it were a single fiber of the same diameter. A collagen molecule consists of three polypeptides wound around one another in a triple helix. A bundle of collagen molecules forms a fibril, and the fibrils are assembled into fibers ([Fig. 10.17](#)). Once multiple collagen fibers are assembled into a ligament or tendon, the final structure is incredibly strong.

**FIG. 10.17 Collagen.** Type I collagen molecules are organized in a triple helix and grouped into bundles called fibrils, which in turn are grouped into bundles called fibers. This type of arrangement, seen in fibers and steel cables, imparts tremendous strength.

The basal lamina is a specialized layer of extracellular matrix that is present beneath all epithelial tissues, including the lining of the digestive tract, epidermis of the skin, and endothelial cells that line the blood vessels of vertebrates ([Fig. 10.18](#)). The basal lamina is made of several proteins, including a special type of collagen. The triple-helical structure of collagen provides flexible support to the epithelial sheet.

## CASE 2 CANCER: CELL SIGNALING, FORM, AND DIVISION

# How do cancer cells spread throughout the body?

Nonmalignant, or benign, tumors are encapsulated masses of cells that divide continuously because regulation of cell division has gone awry ([Chapter 11](#)). As the tumor grows, it pushes outward against adjacent tissues. Benign tumors are rarely life threatening unless the tumor interferes with the function of a vital organ.

Malignant tumors are more dangerous. They contain some cells that can metastasize—that is, break away from the main tumor and travel to distant sites in the body. Metastatic tumor cells have an enhanced ability to adhere to extracellular matrix proteins, especially those in the basal lamina. This is significant because for a cell to metastasize, it must enter and leave the bloodstream through capillaries or other vessels. Since all blood vessels, including capillaries, have a basal lamina, a metastatic tumor cell needs to cross a basal lamina at least twice—once on the way into the bloodstream and again on the way out ([Fig. 10.19](#)). Since cells attach to basal lamina proteins by means of integrins, many studies have compared the integrins in metastatic and non-metastatic cells in the search for potential targets for treatment.

FIG. 10.19 Metastatic cancer cells. Some cancer cells spread from the original site of cancer formation to the bloodstream and then to distant organs of the body.

In some types of cancer, the number of specific integrins on the cell surface is an indicator of metastatic potential. Melanoma provides an

example. A specific type of integrin is present in high amounts on metastatic melanoma cells, but is absent on non-metastatic cells from the same tumor. In laboratory tests, blocking these integrins eliminates the melanoma cell's ability to cross an artificial basal lamina. Drugs targeting this integrin protein are currently in clinical trials.

## Extracellular matrix proteins influence cell shape and gene expression.

Cells continue to interact with the extracellular matrix long after they have synthesized it or moved into it, and these interactions can have profound effects on cell shape and gene expression. Some of these cellular responses are the result of interactions between the extracellular matrix and integrins on the surface of cells. Integrins act as receptors that relay the signal to the cell interior as the first step in this signal transduction pathway ([Chapter 9](#)).

Biologists have studied how the extracellular matrix affects cell shape using cells grown in culture in the laboratory ([Fig. 10.20](#)). For example, fibroblasts cultured on a two-dimensional surface coated with extracellular matrix proteins attach to the matrix and flatten out as they maximize their adhesion to the matrix. By contrast, the same cells cultured in a three-dimensional gel of extracellular matrix look and behave like the spindle-shaped, highly migratory fibroblasts present in living connective tissue ([Fig. 10.20a](#)). Similarly, when nerve cells are grown in culture on a plastic surface, they attach to the surface of the dish but do not take on a neuron-like shape. However, when these cells are grown on the same surface coated with the extracellular matrix protein laminin, they develop long extensions that resemble the axons

and dendrites of normal nerve cells ([Fig. 10.20b](#)).

In addition to influencing cell shape, the structure and composition of the extracellular matrix can influence gene expression, as described in [Fig. 10.21](#). This experiment and the others described here demonstrate that there is a dynamic interplay between the extracellular matrix and the cells that synthesize it.

HOW DO WE KNOW?

**FIG. 10.21**

Can extracellular matrix proteins influence gene

## expression?

### BACKGROUND

Adhesion of cells to the extracellular matrix is required for proper cell shape, as we discussed. In the 1980s, research by Iranian American cell biologist Mina Bissell and colleagues demonstrated that a cell's interaction with extracellular matrix proteins also influences gene expression. Bissell discovered that mammary cells synthesize and secrete high levels of the milk protein b-casein when grown in a three-dimensional collagen matrix but not in a two-dimensional collagen matrix. In the 1990s, American cell biologist Joan Caron followed up these studies using liver cells (hepatocytes).

### HYPOTHESIS

Caron hypothesized that a specific protein in the extracellular matrix is necessary for the expression of the protein albumin from hepatocytes grown in culture. Albumin is a major product of hepatocytes.

### EXPERIMENT

Caron cultured hepatocytes on a thin layer of type I collagen, which does not induce albumin synthesis. Next, she added a mixture of several different extracellular matrix proteins to the culture and looked for changes in albumin gene expression and protein secretion. She then tested individual extracellular matrix proteins from the mixture to see which one was responsible for the increase in albumin gene expression.

### RESULTS

Caron found that when she cultured cells on type I collagen with a combination of three extracellular matrix proteins—laminin, type IV collagen, and heparin sulfate proteoglycan (HSPG)—the cells synthesized high levels of albumin mRNA (top graph, blue line) and albumin protein (middle graph, blue line). However, if she cultured the cells on type I collagen alone, they did not synthesize high levels of albumin mRNA (top

graph, red line) or albumin protein (middle graph, red line). When she tested the three extracellular matrix proteins individually, she found that laminin, but neither of the other proteins (type IV collagen and HSPG), caused an increase in synthesis of albumin mRNA (bottom bar graph).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## CONCLUSION

The experiments supported Caron's hypothesis. A specific extracellular matrix protein, laminin, influences the expression of albumin by

hepatocytes.

#### FOLLOW-UP WORK

Bissell continued her work with mammary cells. She found that laminin increases the expression of the  $\beta$ -casein gene just as it increases expression of the albumin gene in hepatocytes.

#### Self-Assessment Questions

10. Where can extracellular matrix be found in plants and in animals?
11. What are two effects that the extracellular matrix can have on cells?
12. Do you think cadherins or integrins are responsible for the changes in gene expression described in [Fig. 10.21](#)? Why?

## CORE CONCEPTS SUMMARY

**10.1 TISSUES AND ORGANS:** Tissues and organs are communities of cells that perform specific functions.

A tissue is a collection of cells that work together to perform a specific function. [page 203](#)

Two or more tissues often combine to form an organ. [page 203](#)

Cytoskeletal elements determine the shape of the cell. [page 204](#)

Cell junctions connect cells to one another and to the extracellular matrix, a meshwork of proteins and polysaccharides outside the cell. [page 204](#)

**10.2 THE CYTOSKELETON:** The cytoskeleton is composed of microtubules, microfilaments, and intermediate filaments that help maintain cell shape.

Microtubules are hollow polymers of tubulin dimers, and microfilaments are helical polymers of actin monomers. Both microtubules and microfilaments provide structural support to the cell. [page 205](#)

Microtubules and microfilaments are dynamic structures and can assemble and disassemble rapidly. [page 205](#)

Microtubules associate with the motor proteins dynein and kinesin to transport substances in the cell. [page 206](#)

Microfilaments associate with the motor protein myosin to

transport substances in the cell and to cause cell shape changes, such as muscle contraction. [page 207](#)

Microtubules are present in cilia, rodlike structures that extend from the cell surface. Nonmotile cilia often serve a sensory function, whereas motile cilia move cells or fluid surrounding cells. [page 208](#)

Intermediate filaments are polymers of proteins that differ depending on cell type. They provide stable structural support for many types of cells. [page 209](#)

Some prokaryotic cells have protein polymers that function similarly to microtubules and microfilaments. [page 210](#)

**10.3 CELL JUNCTIONS:** Cell junctions connect cells to one another to form tissues.

Cell junctions anchor cells to each other and to the extracellular matrix, allow sheets of cells to act as a barrier, and permit communication between cells in tissues. [page 211](#)

Anchoring cell junctions include adherens junctions and desmosomes. [page 213](#)

Adherens junctions form a belt around the circumference of a cell. They are composed of cell adhesion molecules called cadherins and connect to microfilaments inside the cell. [page 213](#)

Desmosomes are buttonlike points of adhesion between cells. They are composed of cadherins and connect to intermediate filaments inside the cell. [page 213](#)

Hemidesmosomes connect cells to the extracellular matrix. They are composed of integrins and connect to intermediate filaments inside the cell. [page 213](#)

Tight junctions prevent the passage of substances through the space between cells and divide the plasma membrane into apical and basolateral regions. [page 213](#)

Gap junctions (in animals) and plasmodesmata (in plants) allow cells to communicate rapidly with one another. [page 215](#)

**10.4 THE EXTRACELLULAR MATRIX:** The extracellular matrix provides structural support and informational cues.

The extracellular matrix is an insoluble meshwork of proteins and polysaccharides secreted by the cells it surrounds. It provides structural support to cells, tissues, and organs. [page 216](#)

In plants, the extracellular matrix is found in the cell wall, and the main component of the plant cell wall is the polysaccharide cellulose. [page 216](#)

In animals, the extracellular matrix is found in abundance in connective tissue. [page 217](#)

The exceptionally strong protein fiber collagen is the primary component of connective tissues in animals. [page 217](#)

A specialized extracellular matrix called the basal lamina is present underneath all epithelial cell layers. [page 218](#)

The extracellular matrix can influence cell shape and gene

expression. [page 219](#)

# CHAPTER 11 Cell Division

## Variation, Regulation, and Cancer

Dr. Torsten Wittmann/Science Source

---

### CORE CONCEPTS

**11.1 CELL DIVISION:** During cell division, a single parental cell produces two daughter cells.

**11.2 MITOTIC CELL DIVISION:** Mitotic cell division produces genetically identical daughter cells and is the basis for asexual reproduction and development.

**11.3 MEIOTIC CELL DIVISION:** Meiotic cell division produces genetically unique daughter cells and is the basis for sexual reproduction.

**11.4 NONDISJUNCTION:** Nondisjunction results in extra or missing chromosomes.

**11.5 CELL CYCLE REGULATION:** The cell cycle is regulated so that cells divide only at appropriate times and places.

**11.6 CANCER:** Cancer is uncontrolled cell division that can result from mutations in genes that regulate cell division.

---

Cells come from preexisting cells. This is one of the fundamental principles of biology and a key component of the cell theory, which was introduced in [Chapter 5](#). [Cell division](#) is the process by which cells make more cells. Multicellular organisms begin life as a single cell, and then cell division produces the millions, billions, or in the case of humans, trillions of cells that make up the fully developed organism. Even after a multicellular organism has achieved its adult size, cell division continues. In plants, cell division is essential for continued growth. In many animals, cell division replaces worn-out blood cells, skin cells, and cells that line much of the digestive tract. If you fall and scrape your knee, the cells at the site of the wound begin dividing to replace the damaged cells and heal the scrape.

Cell division is also important in reproduction. In bacteria, for example, a new generation is produced when the parent cell divides

and forms two daughter cells. The parent cell first makes two copies of its genetic material. Then the parent cell divides in two so that each of the two daughter cells receives one copy of the genetic material. Reproduction that occurs when offspring receive genetic material from a single parent is called **asexual reproduction**.

By contrast, reproduction that combines the genetic material from two parents is called **sexual reproduction**. Half the genetic material is supplied by the female parent and is contributed by the egg and the other half is supplied by the male parent and is contributed by the sperm. Eggs and sperm are specialized cells called **gametes**. A female gamete and male gamete fuse during fertilization to form a new organism (**Chapter 40**). Gametes are produced by a form of cell division that results in daughter cells with half the number of chromosomes as the parent cell. So when fertilization occurs, the combination of genetic material from the egg and the sperm results in a new organism with the same number of chromosomes as the parents.

What determines when cells divide and, importantly, when they should not? And what determines which cells divide? To answer these questions, we need to understand the process of cell division and how it is controlled. We will then be able to explore how cancer results from a loss of control of cell division.

# 11.1 CELL DIVISION

Cell division is the process by which a single cell produces two daughter cells. In order for a cell to divide successfully, it must be large enough to divide in two and contribute sufficient nuclear and cytoplasmic components to each daughter cell. Before the cell divides, therefore, key cellular components are duplicated. This duplication of material followed by cell division is achieved in a series of steps that constitutes the life cycle of a cell. When you think of a life cycle, you might think of various stages beginning with birth and ending with death. In the case of a cell, the life cycle begins and ends with cell division. In this section, we explore the different ways in which prokaryotic and eukaryotic cells divide.

## Prokaryotic cells divide by binary fission.

Prokaryotic cells produce daughter cells by [binary fission](#). In this form of cell division, a cell replicates its DNA, increases in size, and divides into two daughter cells. Each daughter cell receives one copy of the replicated parental DNA. Binary fission has been studied most extensively in bacteria. The process of binary fission is similar in archaeons as well as in chloroplasts and mitochondria, organelles within plant, fungal, and animal cells that evolved from free-living prokaryotic cells ([Chapters 5 and 25](#)).

Let's consider the process of binary fission in the intestinal bacterium *Escherichia coli* ([Fig. 11.1](#)). The circular genome of *E. coli* is attached by proteins to the inside of the plasma membrane ([Fig. 11.1](#),

[step 1](#)). DNA replication is initiated at a specific location on the circular DNA molecule, called the origin of replication, and proceeds in opposite directions around the circle. The result is two DNA molecules, each attached to the plasma membrane at a different site. The two attachment sites are initially close together ([Fig. 11.1, step 2](#)). The cell then elongates and, as it does so, the two DNA attachment sites move apart ([Fig. 11.1, steps 3 and 4](#)). When the cell is about twice its original size and the DNA molecules are well separated, a constriction forms at the midpoint of the cell ([Fig. 11.1, step 5](#)). Eventually, new membrane and cell wall are synthesized at the site of the constriction, dividing the single cell into two ([Fig. 11.1, step 6](#)). The result is two daughter cells, each having the same genetic material as the parent cell.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 11.1 Binary fission. Prokaryotic cells, such as bacteria and archaeons, divide by binary fission.

Like most cellular processes, binary fission requires the coordination of many components. Recent research has identified several genes whose products play a key role in bacterial cell division. One of these genes, called *FtsZ*, has been especially well studied. *FtsZ* encodes a protein that forms a ring at the site of constriction where the

new cell wall forms between the two daughter cells. *FtsZ* is present in the genomes of diverse bacteria and archaeons, suggesting that it plays a fundamental role in binary fission. Interestingly, it appears to be evolutionarily related to the protein tubulin. Recall from [Chapter 10](#) that tubulin makes up microtubules found in eukaryotic cells that are important in intracellular transport, cell movement, and cell division.

## Eukaryotic cells divide by mitotic cell division.

The basic steps of binary fission that we just saw—replication of DNA, segregation of replicated DNA to daughter cells, and division of one cell into two—occur in all forms of cell division. However, cell division in eukaryotes is more complicated than cell division in prokaryotes. When eukaryotic cells divide, they first divide the nucleus by [mitosis](#) and then divide the cytoplasm into two daughter cells by [cytokinesis](#).

The genome of a prokaryotic cell is a single, relatively small, circular DNA molecule. In comparison, the genome of a eukaryotic cell is typically much larger and is organized into one or more linear chromosomes. Each of these chromosomes must be replicated and separated into daughter cells. The DNA of prokaryotes is attached to the inside of the plasma membrane, allowing replicated DNA to be separated into daughter cells by cell growth. In contrast, the DNA of eukaryotes is located in the nucleus. As a result, eukaryotic cell division requires first the breakdown and then the re-formation of the nuclear envelope, as well as mechanisms other than cell growth to separate replicated DNA. As we saw in [Chapter 10](#) and discuss in more

detail in [section 11.2](#), chromosomes of dividing eukaryotic cells attach to the mitotic spindle, which separates them into daughter cells.

Interestingly, some unicellular eukaryotes exhibit forms of cell division that have characteristics of both binary fission and mitosis. For example, dinoflagellates, like all eukaryotes, have a nucleus and linear chromosomes. However, unlike in most eukaryotes, the nuclear envelope does not break down but stays intact during cell division. Furthermore, the replicated DNA is attached to the nuclear envelope. The nucleus then grows and divides in a manner reminiscent of binary fission. These and other observations of intermediate forms of cell division strongly suggest that mitosis evolved from binary fission.

## The cell cycle describes the life cycle of a eukaryotic cell.

Cell division in eukaryotic cells proceeds through a number of steps that make up the [cell cycle](#) ([Fig. 11.2](#)). The cell cycle consists of two stages: [M phase](#) and [interphase](#). During M phase, the parent cell divides into two daughter cells. M phase consists of two different events: (1) mitosis, the separation of the chromosomes into two nuclei, and (2) cytokinesis, the division of the cell itself into two separate cells. Typically, these two processes go hand in hand, with cytokinesis beginning even before mitosis is complete. In most mammalian cells, M phase lasts about an hour.

FIG. 11.2 The cell cycle. The eukaryotic cell cycle consists of M phase (mitosis and cytokinesis) and interphase.

The second stage of the cell cycle, called interphase, is the time between two successive M phases ([Fig. 11.2](#)). For many years, it was thought that the relatively long period of interphase is uneventful. Today, we know that the cell makes many preparations for division during this stage. These preparations include DNA replication and cell growth. The DNA in the nucleus first replicates so that each daughter cell receives a copy of the genetic material. The cell then increases in size so that each daughter cell receives sufficient amounts of cytoplasmic and membrane components to allow it to survive on its own.

Interphase can be divided into three phases, as shown in [Fig. 11.2](#).

DNA replication occurs during S phase. This phase is called **S phase** because DNA replication involves the synthesis of DNA. In most cells, S phase does not immediately precede or follow mitosis but is separated from it by two gap phases: **G<sub>1</sub> phase** between the end of M phase and the start of S phase, and **G<sub>2</sub> phase** between the end of S phase and the start of M phase. Many essential processes occur during both “gap” phases, despite the name. For example, during G<sub>1</sub>, regulatory proteins, such as kinases, are made. These proteins activate enzymes that synthesize DNA. In G<sub>2</sub>, both the size and protein content of the cell increase. Thus, G<sub>1</sub> is a time of preparation for S-phase DNA synthesis, and G<sub>2</sub> is a time of preparation for M-phase mitosis and cytokinesis.

How long a cell takes to pass through the cell cycle depends on the type of cell and the organism’s stage of development. Most actively dividing cells in your body take about 24 hours to complete the cell cycle. Cells in your skin and intestine that require frequent replenishing usually take about 12 hours. A unicellular eukaryote such as yeast can complete the cell cycle in just 90 minutes. The embryonic cells of some frog species complete the cell cycle even faster. Early cell divisions divide the cytoplasm of the large frog egg cell into many smaller cells and so no growth period is needed between cell divisions. Consequently, there are virtually no G<sub>1</sub> and G<sub>2</sub> phases, and as little as 30 minutes pass between cell divisions.

Not all the cells in your body actively divide. Instead, many cells pause in the cell cycle somewhere between M phase and S phase for periods ranging from days to more than a year. This period is the **G<sub>0</sub>**

**phase** ([Fig. 11.2](#)). It is distinguished from  $G_1$  by the absence of preparations for DNA synthesis. Liver cells remain in  $G_0$  for as much as a year. Other cells such as nerve cells and those that form the lens of the eye enter  $G_0$  permanently; these cells are nondividing. Thus, many brain cells lost to disease or damage cannot be replaced. Although cells in  $G_0$  have exited the cell cycle, they are active in other ways—in particular, cells in  $G_0$  still perform their specialized functions. For example, liver cells in  $G_0$  still carry out metabolism and detoxification.

#### Self-Assessment Questions

1. How is cell division similar and different in prokaryotic cells and eukaryotic cells?
2. What do you predict would be the consequence of a mutation in *FtsZ* that disrupts the function of the protein it encodes?

## 11.2 MITOTIC CELL DIVISION

Mitotic cell division (mitosis followed by cytokinesis) is the basis for asexual reproduction in single-celled eukaryotes, and the means by which an organism's cells, tissues, and organs develop and are maintained in multicellular eukaryotes. During mitosis and cytokinesis, the parental cell's DNA is replicated and passed on to two daughter cells. This process is continuous, but it is divided into discrete steps. These steps are marked by dramatic changes in the cytoskeleton and in the packaging and movement of the chromosomes.

### The DNA of eukaryotic cells is organized as chromosomes.

One of the key challenges faced by a dividing eukaryotic cell is ensuring that the daughter cells receive an equal and complete set of chromosomes. The length of DNA contained in the nucleus of an average eukaryotic cell is on the order of 1 to 2 meters, well beyond the diameter of a cell. The DNA therefore is condensed to fit into the nucleus, and then the DNA is further condensed during cell division so that it does not become tangled as it segregates into daughter cells.

In eukaryotic cells, DNA is organized with histones and other proteins into chromatin, which is packaged to form the structures we know as chromosomes ([Chapters 3](#) and [13](#)). During interphase, chromosomes are long, thin, threadlike structures. One of the earliest events in mitosis is the condensing of chromosomes to short, dense forms that are identifiable under the microscope during M phase.

Every species is characterized by a specific number of chromosomes, and each chromosome contains a single molecule of DNA carrying a specific set of genes. When chromosomes condense and become visible during mitosis, they adopt characteristic shapes and sizes that allow each chromosome to be identified by its appearance in the microscope. The portrait formed by the number and shapes of chromosomes representative of a species is called its **karyotype**. Most of the cells in the human body, with the exception of the gametes, contain 46 chromosomes (**Fig. 11.3**). In contrast, cells of horses have 64 chromosomes, and cells of corn have 20.

In a normal human karyotype, the 46 chromosomes can be arranged

into 23 pairs, 22 pairs of chromosomes numbered 1 to 22 from the longest to the shortest chromosome and 1 pair of sex chromosomes ([Fig. 11.3](#)). Pairs of chromosomes of the same type carrying the same set of genes are said to be **homologous**. One chromosome in each pair was received from the mother and the other from the father. The sex chromosomes are the *X* and *Y* chromosomes. Individuals with two *X* chromosomes are female, and those with an *X* and a *Y* chromosome are male.

The number of complete sets of chromosomes in a cell is known as its ploidy. A cell with one complete set of chromosomes is **haploid**, and a cell with two complete sets of chromosomes is **diploid**. Some organisms, such as plants, can have four or sometimes more complete sets of chromosomes. Such cells are polyploid.

In order for cell division to proceed normally, every chromosome in the parent cell must be duplicated so that each daughter cell receives a full set of chromosomes. This duplication occurs during S phase. Even though the DNA in each chromosome duplicates, the two identical copies, called **sister chromatids**, do not separate. They stay side by side, physically held together at a constriction called the **centromere**. At the beginning of mitosis, the nucleus of a human cell still contains 46 chromosomes, but each chromosome is a pair of identical sister chromatids linked together at the centromere ([Fig. 11.4](#)). Thus, counting chromosomes is simply a matter of counting centromeres.

During mitosis, the sister chromatids separate from each other and go to opposite ends of the cell, so that each daughter cell receives the same number of chromosomes as is present in the parent cell, as we describe now.

## Prophase: Chromosomes condense and become visible.

Mitosis takes place in five stages, each of which is easily identified by events that can be observed in the microscope ([Fig. 11.5](#)). When you look in a microscope at a cell in interphase, you cannot distinguish specific chromosomes because they are long and thin. As the cell moves from  $G_2$  phase to the start of mitosis, the chromosomes condense and become visible in the nucleus. The first stage of mitosis is known as **prophase** and is characterized by the appearance of visible chromosomes ([Fig. 11.5, step 1](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company  
 Source: Jennifer Waters/Science Source.

FIG. 11.5 Mitosis, or nuclear division. Mitosis can be divided into separate steps, but the process is continuous.

Outside the nucleus, in the cytosol, the cell begins to assemble the **mitotic spindle**, a structure made up predominantly of microtubules that pull the chromosomes to opposite ends of the dividing cell. Recall from [Chapter 10](#) that the **centrosome** is a compact structure that is the microtubule organizing center for animal cells. The centrosome is thus the structure from which the microtubules radiate. Plant cells also have a mitotic spindle formed of microtubules, but they lack centrosomes.

During S phase in animal cells, the centrosome duplicates and each one begins to migrate around the nucleus. The two centrosomes ultimately halt at opposite poles in the cell at the start of prophase. The final locations of the centrosomes define the opposite ends of the cell that will eventually be separated into two daughter cells. As the centrosomes make their way to the poles of the cell, tubulin dimers assemble around them, forming microtubules that radiate from each centrosome. These radiating filaments form the mitotic spindle and later serve as the guide wires for chromosome movement.

## Prometaphase: Chromosomes attach to the mitotic spindle.

In the next stage of mitosis, known as **prometaphase**, the nuclear envelope breaks down and the microtubules of the mitotic spindle attach to chromosomes ([Fig. 11.5, step 2](#)). The microtubules radiating from the centrosomes grow and shrink as they explore the region of the cell where the nucleus once was. This process of growing and shrinking depends on the dynamic instability of microtubules, discussed in [Chapter 10](#).

As the ends of the microtubules encounter chromosomes, they attach to the chromosomes at their centromeres. Associated with the centromere of each chromosome are two protein complexes called **kinetochores**, one located on each side of the constriction (**Fig. 11.6**). Each kinetochore is associated with one of the two sister chromatids and forms the site of attachment for a single spindle microtubule. This arrangement ensures that each sister chromatid is attached to a spindle microtubule radiating from one of the poles of the cell. The symmetrical tethering of each chromosome to the two poles of the cell is essential for proper chromosome segregation.

## Metaphase: Chromosomes align as a

## result of dynamic changes in the mitotic spindle.

Once each chromosome is attached to the mitotic spindles from both poles of the cell, the microtubules of the mitotic spindle lengthen or shorten to move the chromosomes to the middle of the cell. There the chromosomes are lined up in a single plane that is roughly equidistant from both poles of the cell. This stage of mitosis, when the chromosomes are aligned in the middle of the dividing cell, is called **metaphase** (see [Fig. 11.5, step 3](#)). It is one of the most visually distinctive stages under the microscope.

## Anaphase: Sister chromatids fully separate.

In the next stage of mitosis, called **anaphase**, the sister chromatids separate (see [Fig. 11.5, step 4](#)). The centromere holding a pair of sister chromatids together splits, allowing the two sister chromatids to separate from each other. After separation, each chromatid is considered to be a full-fledged chromosome. The spindle microtubules attached to the kinetochores gradually shorten, pulling the newly separated chromosomes to the opposite poles of the cell.

After this event, the chromosomes are equally segregated between the two daughter cells. During S phase in a human cell, each of the 46 chromosomes is duplicated to yield 46 pairs of sister chromatids. Then, when the chromatids are separated at anaphase, an identical set of 46 chromosomes arrives at each spindle pole, the complete genetic material for one of the daughter cells.

## Telophase: Nuclear envelopes re-form around newly segregated chromosomes.

Once a complete set of chromosomes arrives at a pole, the chromosomes have entered the area that will form the cytosol of a new daughter cell. This event marks the beginning of **telophase**. During this stage, the cell prepares for its division into two new cells (see [Fig. 11.5, step 5](#)). The microtubules of the mitotic spindle break down and disappear, while a nuclear envelope re-forms around each set of chromosomes, creating two new nuclei. As the nuclei become increasingly distinct in the cell, the chromosomes contained within them decondense, becoming less visible under the microscope. This stage marks the end of mitosis.

## The parent cell divides into two daughter cells by cytokinesis.

Usually, as mitosis is nearing its end, cytokinesis begins and the parent cell divides into two daughter cells ([Fig. 11.7](#)). In animal cells, this stage begins when a ring of actin filaments, called the **contractile ring**, forms against the inner face of the cell membrane at the equator of the cell perpendicular to the axis of what was the spindle ([Fig. 11.7a](#)). As if pulled by a drawstring, the ring contracts, pinching the cytoplasm of the cell and dividing it in two. This process is similar to what occurs in binary fission, although in the case of binary fission, the process is driven by FtsZ protein, a homolog of tubulin, not by actin. The constriction of the contractile ring is driven by motor proteins that slide

bundles of actin filaments in opposite directions. Successful division results in two daughter cells, each with its own nucleus. The daughter cells then enter  $G_1$  phase and start the process again.

---

For the most part, mitosis is similar in animal and in plant cells, but cytokinesis is different ([Fig. 11.7b](#)). Since plant cells have a cell wall, the cell divides in two by constructing a new cell wall. During telophase, dividing plant cells form a structure called the **phragmoplast** in the middle of the cell. The phragmoplast consists of overlapping microtubules that guide vesicles containing cell wall components to the middle of the cell. During late anaphase and telophase, these vesicles fuse to form a new cell wall, called the cell plate, in the middle of the dividing cell. Once this developing cell wall is large enough, it fuses with the original cell wall at the perimeter of the cell. Cytokinesis is then complete and the plant cell has divided into two daughter cells.

#### Self-Assessment Questions

3. Which DNA sequences are more alike: a pair of sister chromatids or a pair of homologous chromosomes?
4. What are three situations in which mitotic cell division occurs?
5. What are the five stages of mitosis? Draw the structure and position of the chromosomes at each stage.
6. What would be the consequence if a cell underwent mitosis but not cytokinesis?
7. How does cytokinesis differ between animal and plant cells?

## 11.3 MEIOTIC CELL DIVISION

As we discussed, mitotic cell division is important in the development of a multicellular organism and in the maintenance and repair of tissues and organs. Mitotic cell division is also the basis of asexual reproduction in unicellular eukaryotes. We now turn to the basis of sexual reproduction. In sexual reproduction, two gametes fuse during fertilization to form a new organism. This new organism has the same number of chromosomes as each of its parents because the two gametes each contain half the number of chromosomes as each diploid parent. Gametes are produced by [meiotic cell division](#), a form of cell division that includes two rounds of nuclear division. By producing haploid gametes, meiotic cell division makes sexual reproduction possible.

There are several major differences between meiotic cell division and mitotic cell division. First, meiotic cell division results in four daughter cells instead of two. Second, each of the four daughter cells contains half the number of chromosomes as the parent cell. (The word “meiosis” is from the Greek for “diminish” or “lessen.”) Third, each of the four daughter cells is genetically unique. In other words, they are genetically different from each other and from the parental cell.

In multicellular animals, the cells produced by meiosis are haploid eggs and sperm. In other organisms, such as fungi, the products are spores, and in some unicellular eukaryotes, the products are new organisms. In this section, we consider the steps by which meiosis occurs, its role in sexual reproduction, and how it likely evolved.

## Pairing of homologous chromosomes is unique to meiosis.

Like mitotic cell division, meiotic cell division follows one round of DNA synthesis, but, unlike mitotic cell division, meiotic cell division consists of two successive cell divisions. The two cell divisions are called [meiosis I](#) and [meiosis II](#), and they occur one after the other. Each cell division results in two cells, so that by the end of meiotic cell division a single parent cell has produced four daughter cells. During meiosis I, homologous chromosomes separate from each other, reducing the total number of chromosomes by half. During meiosis II, sister chromatids separate, as in mitosis.

Meiosis I begins with [prophase I](#), illustrated in [Fig. 11.8](#). The beginning of prophase I is when the condensing chromosomes first become visible. The chromosomes first appear as long, thin threads present throughout the nucleus. Because DNA replication has already taken place, each chromosome has become two sister chromatids held together at the centromere.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 11.8 Prophase I of meiosis. Chromosomes condense and homologous chromosomes pair.

What happens next is an event of enormous importance, and it is unique to meiosis. The homologous chromosomes pair with each other, coming together to lie side by side, gene for gene, in a process known as **synapsis**. Even the X and Y chromosomes pair, but only at the tip, where their DNA sequences are nearly identical. Because one of each pair of homologs is maternal in origin and the other is paternal in origin, chromosome pairing provides an opportunity for the maternal and paternal chromosomes to exchange genetic information, as described in the next section.

Because each homologous chromosome is a pair of sister chromatids attached to a single centromere, a pair of synapsed chromosomes creates a four-stranded structure: two pairs of sister chromatids aligned along their length. The whole unit is called a **bivalent**, and the chromatids attached to different centromeres are called **non-sister chromatids** (Fig. 11.8). Non-sister chromatids result from the replication of homologous chromosomes (one is maternal and the other is paternal in origin), so they have the same set of genes in the same order, but are not genetically identical. By contrast, sister chromatids result from replication of a single chromosome, so are genetically identical.

## Crossing over between DNA molecules results in exchange of genetic material.

Within the bivalents are crosslike structures, each called a **chiasma** (from the Greek meaning a “cross piece”; the plural is “chiasmata”)

([Fig. 11.9](#)). Each chiasma is a visible manifestation of a [crossover](#). A crossover results when non-sister chromatids break and then join in such a way that maternal and paternal genetic material is exchanged.

FIG. 11.9 Chiasmata. Crossing over at chiasmata between non-sister chromatids results in recombinant chromatids.

Through the process of crossing over, homologous chromosomes of maternal origin and paternal origin exchange DNA segments. The positions of these crossovers along the chromosome are essentially random, and therefore each chromosome that emerges from meiosis is unique: it contains some DNA segments from the maternal chromosome and others from the paternal chromosome. The process is very precise: usually, no nucleotides are gained or lost as homologous chromosomes exchange material. Occasionally, the exchange is imprecise and portions of the chromatids may be gained or lost, resulting in duplication or deletion of genetic material. Note the results of crossing over as shown in [Fig. 11.9](#): the recombinant chromatids are those that carry partly paternal and partly maternal segments. By creating new combinations of genes in a chromosome, crossing over

increases genetic diversity.

The number of chiasmata that form during meiosis depends on the species. In humans, the usual range is 50–60 chiasmata per meiosis. Most bivalents have at least one chiasma. Even the *X* and *Y* chromosomes are joined by a chiasma in the small region where they are paired. In addition to their role in exchanging genetic material, the chiasmata also hold the bivalents together while they become properly oriented in the center of the cell during metaphase, the stage we turn to next.

## The first meiotic division reduces the chromosome number.

At the end of prophase I, the chromosomes are fully condensed and have formed chiasmata, the nuclear envelope has begun to disappear, and the meiotic spindle is forming. We are now ready to move through the remaining stages of meiosis I, which are illustrated in [Fig. 11.10](#).

**1 Prophase I (later stage):** Chiasmata present.

**2 Prometaphase I:** Spindles attach to kinetochores on chromosomes.

**3 Metaphase I:** Homologous pairs line up in center of cell, with bivalents oriented randomly with respect to each other.

**4 Anaphase I:** Homologous chromosomes separate, but sister chromatids do not separate.

**5 Telophase I and cytokinesis:** Daughter cells are ready to move into prophase II.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 11.10 Meiosis I. Meiosis I is the reductional division: the number of

chromosomes is halved.

In **prometaphase I**, the nuclear envelope breaks down and the meiotic spindles attach to kinetochores on chromosomes ([Fig. 11.10, step 2](#)).

In **metaphase I**, the bivalents move until they end up on an imaginary plane cutting transversely across the spindle ([Fig. 11.10, step 3](#)). Each bivalent lines up so that its two centromeres lie on opposite sides of this plane, pointing toward opposite poles of the cell. Importantly, the orientation of these bivalents is random with respect to each other. For some, the maternal homolog is attached to the spindle radiating from one pole and the paternal homolog is attached to the spindle originating from the other pole. For others, the orientation is reversed. As a result, when the homologous chromosomes separate from each other in the next stage, a complete set of chromosomes moves toward each pole, and that chromosome set is a random mix of maternal and paternal homologs. The random alignment of maternal and paternal chromosomes in metaphase I further increases genetic diversity in the products of meiosis.

At the beginning of **anaphase I**, the two homologous chromosomes of each bivalent separate as they are pulled in opposite directions ([Fig. 11.10, step 4](#)). The key feature of anaphase I is that the centromeres do not split and the two chromatids that make up each chromosome remain together. Chromatids remain paired because spindle microtubules from one pole of the cell attach to both kinetochores of a given chromosome during prometaphase I. Anaphase I is thus very

different from anaphase of mitosis, in which the centromeres split and each pair of chromatids separates.

Anaphase I ends as the chromosomes arrive at the poles of the cell. Only one of the two homologous chromosomes goes to each pole, so in human cells there are 23 chromosomes (the haploid number of chromosomes) at each pole at the end of meiosis I. Each of these chromosomes consists of two chromatids attached to a single centromere. Meiosis I is sometimes called the **reductional division** because it reduces the number of chromosomes in daughter cells by half.

In **telophase I**, the chromosomes may uncoil slightly and a nuclear envelope briefly reappears ([Fig. 11.10, step 5](#)). In many species (including humans), the cytoplasm divides, producing two separate cells. The chromosomes do not completely decondense, however, and so telophase I blends into the first stage of the second meiotic division. Importantly, there is no DNA synthesis between the two meiotic divisions.

## The second meiotic division resembles mitosis.

Now let's turn to the second meiotic division, meiosis II, shown in [Fig. 11.11](#). In this division, sister chromatids separate. Starting with **prophase II**, the second meiotic division is in many respects like mitotic cell division, except that the nuclei in prophase II have the haploid number of chromosomes, not the diploid number. In prophase II, the chromosomes recondense to their maximum extent. Toward the

end of prophase II, the nuclear envelope begins to disappear (in those species in which it has formed), and the spindle begins to be set up ([Fig. 11.11, step 1](#)).

In [prometaphase II](#), spindles attach to kinetochores ([Fig. 11.11, step 2](#)) and, in [metaphase II](#), the chromosomes line up so that their

centromeres lie on an imaginary plane cutting across the spindle ([Fig. 11.11, step 3](#)).

In **anaphase II**, the centromere of each chromosome splits. The separated chromatids, now each regarded as a full-fledged chromosome, are pulled toward opposite poles of the spindle ([Fig. 11.11, step 4](#)). In this way, anaphase II resembles anaphase of mitosis.

Finally, in **telophase II**, the chromosomes uncoil and become decondensed and a nuclear envelope re-forms around each set of chromosomes ([Fig. 11.11, step 5](#)). The nucleus of each cell now has the haploid number of chromosomes. Because cells in meiosis II have the same number of chromosomes at the beginning and at the end of the process, meiosis II is also called the **equational division**. Telophase II is followed by the division of the cytoplasm in many species.

A comparison of mitosis and meiosis gives us hints about how meiosis might have evolved ([Fig. 11.12](#) and [Table 11.1](#)). During meiosis I, maternal and paternal homologs separate from each other, whereas during meiosis II, sister chromatids separate from each other, similar to mitosis. The similarity of meiosis II and mitosis suggests that meiosis likely evolved from mitosis. Mitosis occurs in all eukaryotes and was certainly present in the common ancestor of all living eukaryotes. Meiosis is present in most, but not all, eukaryotes. Because the steps of meiosis are the same in all eukaryotes, meiosis is thought to have evolved in the common ancestor of all eukaryotes and has been subsequently lost in some groups.

## Division of the cytoplasm often differs between the sexes.

In multicellular organisms, division of the cytoplasm in meiotic cell division differs between the sexes. In female mammals ([Fig. 11.13a](#)), the cytoplasm is divided very unequally in both meiotic divisions. Most of the cytoplasm is retained in one meiotic product, a very large cell called the oocyte. This large cell can develop into the functional egg cell. The other meiotic products receive only small amounts of cytoplasm and are smaller cells called [polar bodies](#). In male mammals ([Fig. 11.13b](#)), the cytoplasm divides about equally in both meiotic divisions, and each of the resulting meiotic products goes on to form a functional sperm. During the development of sperm, most of the cytoplasm is eliminated, and what is left is essentially a nucleus in the sperm head equipped with a long whiplike flagellum to help propel it toward the egg.

FIG. 11.13 Cytoplasmic division in females and in males. (a) In females, cytoplasmic division results in one oocyte and three polar bodies; (b) in males, it results in four sperm cells.

## Meiosis is the basis of sexual reproduction.

Sexual reproduction involves two processes: meiotic cell division and fertilization. Meiotic cell division, as we just saw, produces cells with half the number of chromosomes present in the parent cell. In multicellular animals, the products of meiotic cell division are gametes: an egg cell is a gamete and a sperm cell is a gamete. Each gamete is

haploid, containing a single set of chromosomes. In humans, meiosis takes place in the ovaries of the female and in the testes of the male. Each resulting gamete contains 23 chromosomes, including one each of the 22 numbered chromosomes plus either an *X* or a *Y* chromosome.

During fertilization, these gametes fuse to form a single cell called a **zygote**. The zygote is diploid, having two complete sets of chromosomes, one from each parent. Therefore, fertilization restores the original chromosome number.

As we discuss further in [Chapters 15](#) and [40](#), sexual reproduction plays a key role in increasing genetic diversity. Genetic diversity results from both meiotic cell division and fertilization. The cells produced by meiotic cell division are each genetically different from one another as a result of crossing over and the random alignment and segregation of maternal and paternal chromosomes. In fertilization, different gametes are combined to produce a new, unique individual. Sexual reproduction therefore increases genetic diversity, allowing organisms to evolve and adapt more quickly to their environment than is possible with asexual reproduction.

In the life cycle of multicellular animals such as humans, then, the diploid organism produces single-celled haploid gametes that fuse to make a diploid zygote. In this case, the only haploid cells in the life cycle are the gametes, and the products of meiotic cell division do not undergo mitotic cell division but instead fuse to become a diploid zygote. However, there are a number of life cycles in other organisms that differ in the timing of meiotic cell division and fertilization,

discussed more fully in [Chapter 25](#). Some organisms, such as most fungi, are haploid. These haploid cells can fuse to produce a diploid zygote, but this cell immediately undergoes meiotic cell division to produce haploid cells, so that the only diploid cell in the life cycle is the zygote ([Chapter 32](#)). Other organisms, such as plants, have both multicellular haploid and diploid phases ([Chapter 28](#)). In this case, meiotic cell division produces haploid spores that divide by mitotic cell division to produce a multicellular haploid phase; subsequently, haploid cells fuse to form a diploid zygote that also divides by mitotic cell division to produce a multicellular diploid phase.

#### Self-Assessment Questions

8. In a human cell at the end of prophase I, how many chromatids, centromeres, and bivalents are present?
9. What are three ways in which meiosis I differs from mitosis?
10. What two processes during meiosis result in genetically unique daughter cells?

## 11.4 NONDISJUNCTION

In some cases, errors during mitosis and meiosis can lead to cells with extra or missing chromosomes. These occur quite commonly in humans. They are infrequently observed, however, because most of them are lethal. Nevertheless, a few major chromosomal differences are found in the general population. Some are common enough that their effects are familiar. Others are less common, and a few have no major effects at all. In this section, we focus on the types of difference that are observed, what causes them, and their effects.

### Nondisjunction in meiosis results in extra or missing chromosomes.

**Nondisjunction** is the failure of a pair of chromosomes to separate during anaphase of cell division. The result is that one daughter cell receives an extra copy of one chromosome, and the other daughter cell receives no copy of that chromosome. Nondisjunction can take place in mitosis, and it leads to cell lineages with extra or missing chromosomes, which are often observed in cancer cells ([section 11.6](#)).

When nondisjunction takes place in meiosis, the result is reproductive cells (gametes) that have either an extra or a missing chromosome. **Fig. 11.14** illustrates nondisjunction in meiosis. [Fig. 11.14a](#) shows key stages in a normal meiosis, in which pairs of homologous chromosomes separate in the first division and sister chromatids separate in the second, resulting in gametes that each have one and only one copy of each chromosome.

FIG. 11.14 Nondisjunction. (a) Chromosomes separate evenly into gametes in

normal meiotic cell division. (b) Homologous chromosomes fail to separate in first-division nondisjunction. (c) Sister chromatids fail to separate in second-division nondisjunction.

Failure of chromosome separation can occur in either of the two meiotic divisions. Both types of nondisjunction result in gametes with an extra chromosome or a missing chromosome, but there is an important difference. In **first-division nondisjunction** (Fig. 11.14b), which is much more common, the homologous chromosomes fail to separate and all of the resulting gametes have an extra or missing chromosome. On the other hand, in **second-division nondisjunction** (Fig. 11.14c), sister chromatids fail to separate, giving rise to gametes with an extra chromosome, a missing chromosome, and normal numbers of chromosomes.

## Some human disorders result from nondisjunction.

Approximately 1 out of 155 live-born children (0.6%) has a major chromosome abnormality of some kind. About half of these have a major abnormality in chromosome structure. The others have a chromosome that is present in an extra copy or a chromosome that is missing because of nondisjunction—a parent has produced an egg or a sperm with an extra or a missing chromosome.

Perhaps the most familiar of the conditions resulting from nondisjunction is **Down syndrome**, which results from the presence of an extra copy of chromosome 21. Down syndrome is also known as **trisomy 21** because affected individuals have three copies of

chromosome 21. The extra chromosome can be seen in the chromosome layout called a karyotype ([Fig. 11.15](#)). The shorthand for the condition is  $47, +21$ , meaning that the individual has 47 chromosomes with an extra copy of chromosome 21.

Source: Biophoto Associates/Science Source.

FIG. 11.15 Trisomy 21. This karyotype shows three copies of chromosome 21, which causes Down syndrome.

The presence of an extra chromosome 21 leads to a set of traits that, taken together, constitute a syndrome. These traits result from an increase in the number of genes and other elements present in chromosome 21, and some of these genetic elements have been identified. Children with Down syndrome are mentally disabled to varying degrees; most are in the mild to moderate range and with special education and support they can acquire basic communication,

self-help, and social skills. People with Down syndrome are short because of delayed maturation of the skeletal system, their muscle tone is low, and they have a characteristic facial appearance. About 40% of children with Down syndrome have major heart defects, and life expectancy is currently about 55 years. Among adults with Down syndrome, the risk of dementia is about 15% to 50%, which is about 5 times greater than the risk in the general population.

Although Down syndrome affects approximately 1 in 750 live-born children overall, there is a pronounced effect of mother's age on the risk of Down syndrome. For mothers of ages 45–50, the risk of having a baby with Down syndrome is approximately 50 times greater than it is for mothers of ages 15–20. The increased risk is the reason that many physicians recommend tests to determine abnormalities in the fetus for pregnant women over the age of 35.

Two other trisomies of autosomes (chromosomes other than the X and Y chromosomes) are sometimes found in live births. These are trisomy 13 and trisomy 18. Both are much rarer than Down syndrome and the effects are more severe. In both cases, the developmental abnormalities are so profound that newborns with these conditions usually do not survive the first year of life. Other trisomies of autosomes also occur, but they are not compatible with life.

**Extra or missing sex chromosomes have fewer effects than extra autosomes.**

Children born with an abnormal number of autosomes are rare, but extra or missing sex chromosomes ( $X$  or  $Y$ ) are relatively common among live births. In most mammals, females have two  $X$  chromosomes ( $XX$ ), and males have one  $X$  and one  $Y$  chromosome ( $XY$ ). The presence of the  $Y$  chromosome, not the number of  $X$  chromosomes, leads to male development. The female karyotype 47,  $XXX$  (47 chromosomes, including three  $X$  chromosomes) and the male karyotype 47,  $XYY$  (47 chromosomes, including one  $X$  and two  $Y$  chromosomes) are found among healthy females and males. These individuals are in the normal range of physical development and mental capability, and usually their extra sex chromosome remains undiscovered until their chromosomes are examined for some other reason.

The reason that 47,  $XYY$  males show no detectable effects is the unusual nature of the  $Y$  chromosome. The  $Y$  chromosome contains the gene that stimulates the embryo to take the male developmental pathway and few other genes, so individuals do not have many extra genes, as is the case in Down syndrome. The absence of detectable effects in 47,  $XXX$  females has a completely different explanation that has to do with the manner in which the activity of genes in the  $X$  chromosome is regulated. In the cells of female mammals, all  $X$  chromosomes except one are inactivated and gene expression is largely repressed. (This process, called  $X$ -inactivation, is discussed in [Chapter 19](#).) Because of  $X$ -inactivation, a 47,  $XXX$  female has one active  $X$  chromosome per cell, the same number as in a 46,  $XX$  female.

Two other sex chromosome abnormalities do have effects,

especially on sexual development ([Fig. 11.16](#)). The more common is 47, XXY (47 chromosomes, including two *X* chromosomes and one *Y* chromosome). Individuals with this karyotype are male because of the presence of the *Y* chromosome, but they have a distinctive group of symptoms known as [Klinefelter syndrome](#) ([Fig. 11.16a](#)).

Characteristics of the syndrome are very small testes but normal penis and scrotum. Growth and physical development, for the most part, are normal, although affected individuals tend to be tall for their age.

About half of the individuals have some degree of mental impairment.

When a person with Klinefelter syndrome reaches puberty, the testes fail to enlarge, the voice remains high pitched, pubic and facial hair remains sparse, and there is some enlargement of the breasts. Affected males do not produce sperm and hence are sterile; up to 10% of men who seek aid at infertility clinics turn out to be XXY.

FIG. 11.16 Symptoms associated with (a) Klinefelter syndrome and (b) Turner

syndrome.

Much rarer than all the other sex chromosome abnormalities is 45, X (45 chromosomes, with just one X chromosome), the karyotype associated with characteristics known as [Turner syndrome](#) (Fig. [11.16b](#)). Affected females are short and often have a distinctive webbing of the skin between the neck and shoulders. There is no sexual maturation. The external sex organs remain immature, the breasts fail to develop, and pubic hair fails to grow. Internally, the ovaries are small or absent, and menstruation does not occur. Although the mental abilities of affected females are very nearly normal, they have specific defects in spatial abilities and arithmetical skills.

Earlier we saw that in XX females one X chromosome undergoes inactivation. Why, then, do individuals with just one X chromosome show any symptoms at all? The explanation is that some genes on the inactive X chromosome in XX females are not completely inactivated. Evidently, for normal development to take place, both copies of some genes that escape complete inactivation must be expressed.

Trisomies and the sex-chromosome abnormalities account for most of the simpler chromosomal abnormalities that are found among babies born alive. However, these chromosomal abnormalities represent only a minority of those that actually occur. In fertilized eggs with extra or missing chromosomes, the embryos usually fail to complete development. At some time during pregnancy—in some cases very early, in other cases relatively late—the chromosomally abnormal embryo or fetus undergoes spontaneous abortion.

### Self-Assessment Questions

11. How does nondisjunction in meiosis I or II result in extra or missing chromosomes? Make a diagram to answer the question.
12. A male baby is born with the sex-chromosome constitution  $XYY$ . Both parents have normal sex chromosomes ( $XY$  in the father,  $XX$  in the mother). In which meiotic division of which parent did the nondisjunction take place that produced the  $XYY$  baby?

# 11.5 CELL CYCLE REGULATION

Cell division occurs only at certain times and places. Mitotic cell division, for example, occurs as a multicellular organism grows, a wound heals, or cells are replaced in actively dividing tissues such as the skin or lining of the intestine. Similarly, meiotic cell division occurs only at certain times during development. Even for unicellular organisms, cell division takes place only when conditions are favorable—for example, when enough nutrients are present in the environment. In all these cases, a cell may have to receive a signal before it divides. In [Chapter 9](#), we saw how cells respond to signals. Growth factors, for example, bind to cell-surface receptors and activate intracellular signaling pathways that lead to cell division.

Even when a cell receives a signal to divide, it does not divide until it is ready. Has all of the DNA been replicated? Has the cell grown large enough to support division into viable daughter cells? If these and other preparations have not been accomplished, the cell halts its progression through the cell cycle.

So, cells have regulatory mechanisms that initiate cell division, as well as mechanisms for spotting faulty or incomplete preparations and arresting cell division. When these mechanisms fail—for example, dividing in the absence of a signal or when the cell is not ready—the result may be uncontrolled cell division, a hallmark of cancer. In this section, we consider how cells control their passage through the cell cycle. Our focus is on control of mitotic cell division. However, many

of the same factors also regulate meiotic cell division, a reminder of the close evolutionary connection between these two forms of cell division.

## Protein phosphorylation controls passage through the cell cycle.

Early animal embryos, such as those of frogs and sea urchins, are useful model organisms for studying cell cycle control because they are large and undergo many rapid mitotic cell divisions following fertilization. During these rapid cell divisions, mitosis and S phase alternate with virtually no  $G_1$  and  $G_2$  phases in between. Studies of animal embryos revealed two interesting patterns. First, as the cells undergo this rapid series of divisions, several proteins appear and disappear in a cyclical fashion. Researchers hypothesized that these proteins might play a role in controlling the progression through the cell cycle. Second, several enzymes become active and inactive in cycles. These enzymes are kinases, proteins that phosphorylate other proteins ([Chapter 9](#)). The timing of kinase activity is delayed slightly relative to the appearance of the cyclical proteins.

These and many other observations led to the following view of cell cycle control. Proteins are synthesized that activate the kinases. These regulatory proteins are called [cyclins](#) because their levels rise and fall with each turn of the cell cycle. Once activated by cyclins, the kinases phosphorylate target proteins that promote cell division ([Fig. 11.17](#)). These kinases, called [cyclin-dependent kinases](#) (CDKs), are always present within the cell but are active only when bound to the appropriate cyclin. It is the kinase activity of the cyclin–CDK

complexes that triggers cell cycle events. In sum, the cyclical activity of the cyclin–CDK complexes depends on the cyclical levels of the cyclins. Cyclins in turn may be synthesized in response to signaling pathways that promote cell division.

These cell cycle proteins, including cyclins and CDKs, are widely

conserved across eukaryotes, reflecting their fundamental role in controlling cell cycle progression, and have been extensively studied in yeast, sea urchins, mice, and humans ([Fig. 11.18](#)).

#### HOW DO WE KNOW?

### FIG. 11.18

## How is progression through the cell cycle controlled?

#### BACKGROUND

Many components of the cell undergo cyclical changes during the cell cycle: chromosomes condense and decondense, the mitotic spindle forms and breaks down, and the nuclear envelope breaks down and re-forms. How these regular and cyclical changes are controlled is the subject of active research.

The first clues came from studies of yeast. Mutations in certain yeast genes blocked progression through the cell cycle, suggesting that these genes encode proteins that normally promote progression through the cell cycle. Additional clues came from studies of embryos of the sea urchin *Arbacia punctulata*. These embryos are large and divide rapidly by mitosis, so they are a good model system for the study of cell division. In the early 1980s, it was known that inhibition of protein synthesis blocks cell division in sea urchins. It was also known that an enzyme called MPF, or M-phase promotion factor, is necessary for the transition from **G<sub>2</sub>** to M phase.

SOURCE: *SeaPics.com*.

#### EXPERIMENT

In the 1980s, English biochemist Tim Hunt and colleagues measured protein levels in sea urchin embryos as they divide rapidly by mitosis. The researchers added radioactive methionine (an amino acid) to eggs, which became incorporated into newly synthesized proteins. The eggs were then fertilized and allowed to develop. Samples of the rapidly dividing embryos were taken every 10 minutes. Extracts of these embryos were made. These extracts were loaded into wells of a gel. An electrical charge was then applied to the gel, causing the proteins to migrate toward one end of the gel and separating them according to their charge and size. This technique allowed the researchers to visualize the levels of different proteins.

#### RESULTS

Most protein bands became darker as cell division proceeded, indicating more and more protein synthesis. However, the level of one protein band oscillated, increasing in intensity and then decreasing with each cell cycle, as shown in the graph.

## CONCLUSION

Hunt and colleagues called this oscillating protein “cyclin.” Although they did not know its function, its fluctuating levels suggested it might play a role in the control of the cell cycle. More work was needed to figure out if cyclins actually cause progression through the cell cycle or if cyclin levels fluctuate in response to progression through the cell cycle.

## FOLLOW-UP WORK

Hunt and colleagues found a similar rise and fall in the levels of certain proteins in the sea urchin *Lytechinus pictus* and surf clam *Spisula solidissima* that they had found in *Arbacia punctulata*. MPF was found to consist of a cyclin protein and a cyclin-dependent kinase (CDK) that play a key role in the G<sub>2</sub>–M transition. Together, these experiments suggested that cyclins control progression through the cell cycle by their interactions with cyclin-dependent kinases. Hunt shared the Nobel Prize in Physiology or Medicine in 2001 for his work on cyclins.

SOURCE T. Evans et al. 1983. “Cyclin: A Protein Specified by Maternal mRNA in Sea

## Different cyclin–CDK complexes regulate each stage of the cell cycle.

In mammals, there are several different cyclins and CDKs that act at specific steps of the cell cycle. Three steps in particular are regulated by cyclin–CDK complexes in all eukaryotes ([Fig. 11.19](#)).

FIG. 11.19 Cyclin–CDK complexes. Cyclin–CDK complexes are active at different times in the cell cycle.

During G<sub>1</sub>, levels of cyclin D and cyclin E rise and activate CDKs, which allows the cell to enter S phase. These cyclin–CDK complexes

activate transcription factors that lead to the expression of histone proteins needed for packaging the newly replicated DNA strands. They also result in expression and activation of DNA polymerase and the other enzymes that function during DNA replication.

During S phase, levels of cyclin A rise, activating CDKs that inhibit activity of the DNA synthesis enzymes once DNA replication is complete, which prevents the replication proteins from reassembling at the same place and re-replicating the same DNA sequence. Synthesizing the same sequence repeatedly would be dangerous because cells with too much DNA could die or become cancerous.

During  $G_2$ , cyclin B levels rise and activate CDKs that activate enzymes that initiate multiple events associated with mitosis. For example, cyclin B–CDK complex phosphorylates structural proteins in the nucleus, triggering the breakdown of the nuclear envelope in prometaphase. Cyclin B–CDK also phosphorylates proteins that regulate the assembly of tubulin into microtubules, promoting the formation of the mitotic spindle.

## Cell cycle progression requires successful passage through multiple checkpoints.

Cyclins and CDKs not only allow a cell to progress through the cell cycle, but also give the cell opportunities to halt the cell cycle should something go wrong. For example, the preparations for the next stage of the cell cycle may be incomplete or there may be some kind of

damage. In these cases, there are mechanisms that block the cyclin–CDK activity required for the next step, pausing the cell cycle until preparations are complete or the damage is repaired. Each of these mechanisms is called a **checkpoint**.

Cells have many cell cycle checkpoints. **Fig. 11.20** shows three major checkpoints. The presence of damaged DNA arrests the cell at the end of  $G_1$  before DNA synthesis, the presence of unreplicated DNA arrests the cell at the end of  $G_2$  before the cell enters mitosis, and abnormalities in chromosome attachment to the spindle arrest the cell in early mitosis. By way of illustration, we focus on the checkpoint that occurs at the end of  $G_1$  in response to the presence of damaged DNA.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 11.20 Cell cycle checkpoints. Cell cycle checkpoints monitor key steps in the cell cycle.

DNA can be damaged by environmental insults such as ultraviolet radiation or chemical agents ([Chapter 14](#)). Typically, damage takes the form of double-stranded breaks in the DNA. If the cell progresses through mitosis with DNA damage, daughter cells might inherit the damage, or the chromosomes might not segregate normally. The checkpoint late in **G<sub>1</sub>** delays progression through the cell cycle until DNA damage is repaired. This DNA damage checkpoint depends on several regulatory proteins: some of these recognize damaged DNA, whereas others arrest cell cycle progression before S phase.

When DNA is damaged by radiation, a specific protein kinase is activated that phosphorylates a protein called p53. Phosphorylated p53 binds to DNA, where it turns on the expression of several genes. One of these genes codes for a protein that binds to and blocks the activity of the G<sub>1</sub>/S cyclin–CDK complexes ([Fig. 11.21](#)). In so doing, p53 arrests the cell at the G<sub>1</sub>/S transition, giving the cell time to repair the damaged DNA. The p53 protein therefore is a good example of a protein involved in halting the cell cycle when the cell is not ready to divide. Because of its role in protecting the genome from accumulating DNA damage, p53 is sometimes called the “guardian of the genome.” Mutations in p53 are common in cancer, a topic we turn to next.

FIG. 11.21 DNA damage checkpoint controlled by p53.

### Self-Assessment Questions

13. What are the roles of cyclins and cyclin-dependent kinases in the cell cycle?
14. What are three examples of checkpoints that the cell monitors before proceeding through the cell cycle?

## 11.6 CANCER

---

### CASE 2 CANCER: CELL SIGNALING, FORM, AND DIVISION

## What genes are involved in cancer?

As we have seen, cells have evolved mechanisms that promote passage through the cell cycle, such as the cyclin–CDK complexes, as well as mechanisms that halt the cell cycle when the cell is not ready to divide, such as the DNA damage checkpoint that depends on the p53 protein. When cellular mechanisms that promote cell division are activated inappropriately or the normal checks on cell division are lost, cells may divide uncontrollably. The result can be cancer, a group of diseases characterized by uncontrolled cell division.

In this section, we explore various ways in which cell cycle control can fail and lead to cancer. We begin with a discussion of a cancer caused by a virus. Although viruses are not the cause of most cancers, the study of these cancers helped us to understand how cancers develop.

## Oncogenes promote cancer.

Our understanding of cancer is based partly on early observations of cancers in animals. In the first decade of the twentieth century, Peyton Rous studied cancers called sarcomas in chickens ([Fig. 11.22](#)). His work and that of others led to the discovery of the first virus known to

cause cancer in animals, named the Rous sarcoma virus.

#### HOW DO WE KNOW?

### FIG. 11.22

## Can a virus cause cancer?

#### BACKGROUND

In the early 1900s, little was known about the cause of cancer or the nature of viruses. Peyton Rous, an American pathologist, studied a form of cancer called a sarcoma in chickens. He moved a cancer tumor from a diseased chicken to a healthy chicken and found that the cancer could be transplanted. Rous then decided to conduct a further experiment to determine if a cell-free extract of the tumor injected into a healthy chicken could also induce cancer.

#### HYPOTHESIS

Experiments in other organisms, such as mice, rats, and dogs, showed that an extract free of cells from a tumor does not cause cancer. Therefore, Rous hypothesized that a cell-free extract of the chicken sarcoma would not induce cancer in healthy chickens.

#### EXPERIMENT

Rous took a sample of the sarcoma from a chicken, ground it up, suspended it in solution, and centrifuged it to remove the debris. In his first experiment, he injected this extract into a healthy chicken. In a second experiment, he passed the extract through a filter to remove all cells, including cancer cells and bacterial cells, and then injected this cell-free extract into a healthy chicken.

## RESULTS

In both cases, healthy chickens injected with the extract from the sarcoma developed cancer at the site of injection. Microscopic examination of the cancer showed it to be the same type of cancer as the cancer from the original chicken.

## CONCLUSION AND FOLLOW-UP WORK

Because the extract that did not contain any cells did cause cancer in chickens, Rous rejected his hypothesis. He concluded that an agent smaller than a cell, such as a virus or chemical, is capable of causing cancer. Later experiments confirmed that the cause of chicken sarcoma is a virus. This result was surprising, controversial, and dismissed at the time. A second cancer-causing virus was not found until the 1930s. Although most cancers are not caused by viruses, work with cancer-causing viruses helped to identify cellular genes that, when mutant, can lead to cancer. In 1966, Rous shared the Nobel Prize in Physiology or Medicine for his discovery.

SOURCES Rous, P. 1910. "A Transmissible Avian Neoplasm (Sarcoma of the Common Fowl)." *J. Exp. Med.* 12:696–705; Rous, P. 1911. "Transmission of a malignant new growth by means of a cell-free filtrate." *JAMA* 56:198.

All viruses have a protein coat surrounding a core of either RNA or DNA ([Chapter 1](#)). Viruses multiply by infecting cells and using the biochemical machinery of the host cell to synthesize viral components, which are assembled to make more copies of themselves. The investigation of cancer-causing viruses provided major insights into how cancers form. Because viruses typically carry only a handful of genes, it is relatively easy to identify which of those genes is a factor in causing cancer.

As discussed in [Chapter 9](#), growth factors activate several types of proteins inside the cell that promote cell division. The gene from the Rous sarcoma virus that promotes uncontrolled cell division encodes an overactive protein kinase similar to the kinases in the cell that function as signaling proteins. This viral gene is named *v-src*, for *viral-src* (pronounced “sarc” and short for “sarcoma,” the type of cancer it causes).

The *v-src* gene is one of several examples of an [oncogene](#), or cancer-causing gene, found in viruses. A real surprise was the discovery that the *v-src* oncogene is found not just in the Rous sarcoma virus. It is an altered version of a gene normally found in the host animal cell, known as *c-src* (*cellular-src*). The *c-src* gene plays a role in the normal control of cell division during embryonic development.

**Proto-oncogenes are genes that when mutated may cause cancer.**

The discovery that the *v-src* oncogene has a normal counterpart in the host cell was an important step toward identifying the cellular genes

that participate in cell growth and division. These normal cellular genes are called [proto-oncogenes](#). They are involved in cell division. Nearly every protein that performs a key step in a signaling cascade that promotes cell division can be the product of a proto-oncogene. These include growth factors, cell-surface receptors, G proteins, and protein kinases. Each of these can be mutated to become oncogenes. However, proto-oncogenes do not themselves cause cancer. Only when they are mutated do they have the potential to cause cancer. Today, we know of scores of proto-oncogenes. Most were identified through the study of cancer-causing viruses in chickens, mice, and cats.

Oncogenes also play a major role in human cancers. Most human cancers are not caused by viruses. Instead, human proto-oncogenes can be mutated into cancer-causing oncogenes by environmental agents such as chemical pollutants. For example, organic chemicals called aromatic amines present in cigarette smoke can enter cells and damage DNA, resulting in mutations that can convert a proto-oncogene into an oncogene.

Let's consider an example of a proto-oncogene. In [Chapter 9](#), we discussed platelet-derived growth factor, or PDGF. This protein binds to and dimerizes a receptor kinase in the membrane of the target cell. The dimerized receptor activates several signaling pathways that together promote cell division. In one type of leukemia (a cancer of blood cells), a mutation occurs in the gene that encodes the PDGF receptor. The mutant receptor is missing the extracellular portion needed to bind the growth factor and dimerizes on its own, independent of PDGF binding. The receptor is therefore always turned on. The

overactive PDGF receptor activates too many target proteins over too long a time period, leading to uncontrolled proliferation of blood cells.

## Tumor suppressors block specific steps in the development of cancer.

Up to this point, we have considered what happens when mechanisms that promote cell division are inappropriately activated. Now let's consider what happens when mechanisms that usually prevent cell cycle progression are removed.

Earlier, we discussed cell cycle checkpoints that halt the cell cycle until the cell is ready to divide. One of these checkpoints depends on the p53 protein, which normally arrests cell division in response to DNA damage ([section 11.4](#)). When the p53 protein is mutated or its function is inhibited, the cell can divide before the DNA damage is repaired. Such a cell continues to divide in the presence of damaged DNA, leading to the accumulation of mutations that promote cell division. The p53 protein is mutated in many types of human cancer, highlighting its critical role in regulating the cell cycle.

The p53 protein is one example of a [tumor suppressor](#). Tumor suppressors are proteins whose normal activities inhibit cell division. Some tumor suppressors participate in cell cycle checkpoints, as is the case for p53. Other tumor suppressors repress the expression of genes that promote cell division, and still others trigger cell death.

Tumor suppressors act in opposition to proto-oncogenes. Therefore, whether a cell divides or not depends on the activities of both proto-

oncogenes and tumor suppressors: proto-oncogenes must be turned on and tumor suppressors must be turned off for a cell to divide. Given the importance of controlling cell division, it is not surprising that cells have two counterbalancing systems that must be in agreement before cell division takes place.

## Most cancers require the accumulation of multiple mutations.

Most human cancers require more than the overactivation of one oncogene or the inactivation of a single tumor suppressor. Given the multitude of different tumor suppressor proteins that are produced in the cell, it is likely that one will compensate for even the complete loss of another. Cells have evolved a redundant arrangement of these control mechanisms to ensure that cell division is properly regulated.

When several different cell cycle regulators fail, leading to both the overactivation of oncogenes and the loss of tumor suppressor activity, cancer will likely develop. The cancer may be either benign or malignant. A benign cancer is relatively slow growing and does not invade the surrounding tissue, whereas a malignant cancer grows rapidly and invades surrounding tissues. In many cases of malignant colon cancer, for example, tumor cells contain at least one overactive oncogene and several inactive tumor suppressor genes ([Fig. 11.23](#)). The gradual accumulation of these mutations over a period of years can be correlated with the stepwise progression of the cancer from a benign to a malignant cancer.

Company

FIG. 11.23 Multiple-mutation model for the development of cancer. Cells that become cancerous typically carry mutations in several different genes.

Taken together, we can now define some of the key characteristics that make a cell cancerous. Uncontrolled cell division is certainly important, but given the communities of cells and extracellular matrix we have discussed over the last few chapters, we should also consider additional characteristics. In 2000, American biologists Douglas Hanahan and Robert Weinberg highlighted key features of cancer cells. These include the ability to divide on their own in the absence of growth signals, resistance to signals that inhibit cell division or promote cell death, the ability to invade local and distant tissues (metastasis), and the production of signals to promote new growth of blood vessels for delivering nutrients to support cell division.

Considered in this light, a cancer cell is one that no longer plays by the “rules” of a normal cellular community. Cancer therefore serves to remind us of the normal controls and processes that allow cells to exist in a community. These processes, which work together, are summarized in [Fig. 11.24](#) on the following pages.

### Self-Assessment Questions

15. How do oncogenes, proto-oncogenes, and tumor suppressor genes differ from one another?
16. What are two ways in which the function of p53 can be disrupted?

## CORE CONCEPTS SUMMARY

**11.1 CELL DIVISION:** During cell division, a single parental cell produces two daughter cells.

Prokaryotic cells divide by binary fission, in which a cell replicates its DNA, segregates its DNA, and divides into two cells. [page 225](#)

Eukaryotic cells divide by mitosis (nuclear division) and cytokinesis (cytoplasmic division). Together, mitosis and cytokinesis are known as mitotic cell division. [page 226](#)

The cell cycle is divided into M phase, which consists of mitosis and cytokinesis, and interphase, which consists of  $G_1$ , S (synthesis), and  $G_2$  phases. [page 227](#)

Cells that do not need to divide exit the cell cycle and are in  $G_0$ . [page 227](#)

**11.2 MITOTIC CELL DIVISION:** Mitotic cell division produces genetically identical daughter cells and is the basis for asexual reproduction and development.

DNA in a eukaryotic cell is packaged as linear chromosomes. [page 228](#)

Humans have 23 pairs of chromosomes, or 46 chromosomes total, including 1 pair of sex chromosomes. [page 228](#)

Homologous chromosomes are chromosomes of the same type with the same set of genes. [page 228](#)

Each parent contributes one complete set of 23 chromosomes at fertilization. [page 228](#)

During S phase, chromosomes replicate, forming a pair of sister chromatids held together at the centromere. [page 228](#)

Mitosis consists of five steps following DNA replication: (1) prophase—the chromosomes condense and become visible under the light microscope, (2) prometaphase—the spindle microtubules attach to the centromeres, (3) metaphase—the chromosomes line up in the middle of the cell, (4) anaphase—the centromeres split and the chromosomes move to opposite poles, and (5) telophase—the nuclear envelope re-forms and chromosomes decondense. [page 228](#)

Mitosis is followed by cytokinesis, in which one cell divides into two. In animals, a contractile ring of actin pinches the cell in two. In plants, a new cell wall, called the cell plate, is synthesized between the daughter cells. [page 230](#)

**11.3 MEIOTIC CELL DIVISION:** Meiotic cell division produces genetically unique daughter cells and is the basis for sexual reproduction.

Sexual reproduction involves meiosis and fertilization, both of which are important in increasing genetic diversity. [page 231](#)

Meiotic cell division is a form of cell division that reduces the number of chromosomes by half. It produces haploid gametes or spores that have one copy of each chromosome. [page 231](#)

Fertilization is the fusion of haploid gametes to produce a diploid cell. [page 231](#)

Meiosis consists of two successive cell divisions: the first is reductional (the chromosome number is halved), and the second is equational (the chromosome number stays the same). Each division consists of prophase, prometaphase, metaphase, anaphase, and telophase. [page 231](#)

In meiosis I, homologous chromosomes pair and exchange genetic material at chiasmata, or regions of crossing over. In contrast to mitosis, centromeres do not split and sister chromatids do not separate. [page 232](#)

Meiosis II is similar to mitosis in that chromosomes align in the center of the cell, centromeres split, and sister chromatids separate from each other. [page 234](#)

The similarity of meiosis II and mitosis suggests that meiosis evolved from mitosis. [page 235](#)

The division of the cytoplasm differs between the sexes: male meiotic cell division produces four functional sperm cells, whereas female meiotic cell division produces a single functional egg cell and three polar bodies. [page 235](#)

Genetic diversity is generated by (1) crossing over and (2) random alignment and subsequent segregation of maternal and paternal homologs in meiosis I. [page 237](#)

**11.4 NONDISJUNCTION:** Nondisjunction results in extra or missing

chromosomes.

Nondisjunction is the failure of a pair of chromosomes to separate during anaphase of cell division. It can occur in mitosis or meiosis and results in daughter cells with extra or missing chromosomes.

[page 238](#)

Nondisjunction in meiosis leads to gametes with extra or missing chromosomes. [page 239](#)

Most human fetuses with extra or missing chromosomes spontaneously abort, but some are viable and exhibit characteristic syndromes. [page 239](#)

Trisomy 21 (Down syndrome) is usually characterized by three copies of chromosome 21. [page 239](#)

Extra or missing sex chromosomes ( $X$  or  $Y$ ) are common and result in syndromes such as Klinefelter syndrome (47,  $XXY$ ) and Turner syndrome (45,  $X$ ). [page 240](#)

**11.5 CELL CYCLE REGULATION:** The cell cycle is regulated so that cells divide only at appropriate times and places.

Cells have regulatory mechanisms for promoting and preventing cell division. [page 241](#)

Levels of proteins called cyclins increase and decrease during the cell cycle. [page 241](#)

Cyclins form complexes with cyclin-dependent kinases (CDKs), activating the CDKs to phosphorylate target proteins that promote

cell division. [page 241](#)

Cyclin–CDK complexes are activated by signals that promote cell division. [page 242](#)

Different cyclin–CDK complexes control progression through the cell cycle at key steps, including G<sub>1</sub>/S phase, S phase, and M phase. [page 243](#)

The cell has checkpoints that halt progression through the cell cycle if something is not right. [page 243](#)

The p53 protein is an example of a checkpoint protein; it prevents cell division in the presence of DNA damage. [page 244](#)

**11.6 CANCER:** Cancer is uncontrolled cell division that can result from mutations in genes that regulate cell division.

Cancer results when mechanisms that promote cell division are inappropriately activated or the normal checks on cell division are lost. [page 245](#)

Cancers can be caused by certain viruses carrying oncogenes that promote uncontrolled cell division. [page 245](#)

Viral oncogenes have cellular counterparts called proto-oncogenes that play normal roles in cell growth and division and that, when mutated, can cause cancer. [page 245](#)

Oncogenes and proto-oncogenes often encode proteins involved in signaling pathways that promote cell division. [page 245](#)

Tumor suppressors encode proteins, such as p53, that block cell

division and inhibit cancers. [page 245](#)

Cancers usually result from several mutations in proto-oncogenes and tumor suppressor genes that have accumulated over time within the same cell. [page 247](#)

---

## CASE 3

### Your Personal Genome

*You, from A to T*

As an American studies major at Georgetown University, Claudia Gilmore had plenty of experience taking exams. But at the age of 21, she faced an altogether different kind of test—and no amount of studying could have prepared her for the result. Gilmore had decided to be tested for a mutation in a gene known as *BRCA1*. Specific mutations in the *BRCA1* and *BRCA2* genes are associated with an increased risk of breast and ovarian cancers.

*Source: Photo by Dominic Gutierrez, courtesy Claudia Gilmore.*

Answers in the genetic sequence. Claudia Gilmore found that her genome

contains a mutation that can lead to breast cancer.

In 2003, scientists published the first draft of the complete human genome. The human genome consists of a complete set of 23 chromosomes containing about 3 billion base pairs of DNA. Since then, genetic testing has become increasingly common and in some cases routine.

*Mutations that increase the risk of developing a particular disease are called genetic risk factors.*

Gilmore's grandmother had battled breast cancer and later died from ovarian cancer. Before her death, she had tested positive for the

*BRCA1* mutation. Her son, Gilmore's father, was tested and discovered he had inherited the mutation. After talking with a genetic counselor to help her understand the implications of the test, Gilmore gave a sample of her own blood and crossed her fingers.

"I had a fifty-fifty chance of inheriting the mutation. I knew there was a great possibility it would be a part of my future," she says. "But I was 21, I was healthy. A part of me also thought this could never really happen to me."

Unfortunately, it could. Two weeks after her blood was drawn, she learned that she, too, carried the mutated gene.

In reality, there isn't one single human genome. Everyone on Earth

(with the exception of identical twins) has his or her own unique genetic sequence. Your personal genome, consisting of two sets of chromosomes, is the blueprint that codes for your hair color, the length of your nose, and your susceptibility to certain diseases. On average, any two human genomes are 99.9% identical, meaning that they differ at about 3 million base pairs.

Oftentimes, those differences have no impact on health. In some cases, however, a particular genetic signature is associated with disease. Sometimes a mutation makes a given illness inevitable. Certain mutations in a gene called *HTT*, for instance, always result in Huntington's disease, a degenerative brain condition that usually appears in middle age.

The link between mutations and disease isn't always so clear-cut, however. Most genetic diseases are complex, and it may take multiple mutations as well as other nongenetic factors for the disease to develop. Mutations that increase the risk of developing a particular disease are called genetic risk factors.

Certain mutations in the *BRCA1* and *BRCA2* genes are known genetic risk factors for breast and ovarian cancers, for instance. But not everyone with these mutations develops cancer. According to the National Cancer Institute, about 60% of women with a harmful *BRCA1* mutation will develop breast cancer in her lifetime, compared with about 12% of women in the general population. And 15% to 40% of women with a *BRCA1* mutation will be diagnosed with ovarian cancer, compared with just 1.4% of women without that genetic change.

What does your genome say about you? Researchers have identified genes that, when mutated, contribute to disease, as well as differences that help reveal who you are and where you come from.

The *BRCA1* mutations are just some of the thousands of harmful genetic changes that geneticists have identified so far. Other common mutations have been shown to elevate one's risk of developing heart disease, diabetes, various cancers, and numerous other common illnesses. Often, these mutations involve changes to just a single base pair of DNA. These common single-letter mutations are known as single nucleotide polymorphisms, or SNPs.

Several companies now offer genetic tests directly to the public. Unlike tests such as the *BRCA1* blood test that Gilmore was given,

these direct-to-consumer (DTC) tests are offered to customers without any involvement of a medical professional, at a cost of a few hundred dollars.

Some of these tests aren't related to health. Your personal genome contains sequences that help to determine many unique features—from the shape of your fingernails to the shade of your skin—that don't affect your health but make you in part the person you are. Some DTC testing services aim to tell customers about their history by screening genes to identify variations that are more common in certain geographical regions or among members of certain ethnic groups. One such company offers genetic tests to African-Americans to determine in what part of the African continent their ancestors originated.

Other popular DTC tests inspect DNA samples for SNPs associated with certain diseases and physical traits—everything from Parkinson's disease and age-related macular degeneration to earwax type and propensity for baldness.

Advocates of the tests say the technology puts the power of genetic information in the hands of consumers. Critics, on the other hand, argue that the information provided by DTC tests isn't always very meaningful. The presence of some SNPs might raise the risk of a rare disease by just 2% or 3%, for example. In many cases, the precise link between mutation and disease is still being sorted out. Also, without input from a genetic counselor or medical professional, consumers may not know how to interpret the information revealed by the tests. The American Medical Association has recommended that a doctor always

be involved when any genetic testing is performed.

Moreover, knowing your genetic risk factors isn't the whole story. When it comes to your health and well-being, the environment also plays a significant role. Someone might override a genetic predisposition for skin cancer by using sunscreen faithfully every day. On the other hand, a person might have a relatively low genetic risk for type 2 diabetes, but still boost the odds of developing the disease by eating a poor diet and getting little physical exercise.

Claudia Gilmore is especially careful to exercise regularly and eat a healthy diet. Still, she can only control her environment to a degree. She knew that, given her genetic status, her risk of breast cancer remained high. She made the extraordinary decision to eliminate that risk by undergoing a mastectomy at the age of 23. It wasn't an easy decision, she says, but she feels privileged to have been able to take proactive steps to protect her health. "I'll be a 'previvor' instead of a survivor," she says.

Two years later the same medical choice was made by the American actress, film director, screenwriter, and author Angelina Jolie. She recounted her experience in *The New York Times*, writing, "Once I knew that this [*BRCA1* mutation] was my reality, I decided to be proactive and to minimize the risk as much I could. I made a decision to have a preventive double mastectomy. I started with the breasts, as my risk of breast cancer is higher than my risk of ovarian cancer, and the surgery is more complex. . . . I am writing about it now because I hope that other women can benefit from my experience."<sup>1</sup>

An unintended consequence of Jolie's public disclosure was that some women interpreted it as an endorsement. Immediately afterward, there was a brief surge in *BRCA1* and *BRCA2* testing. Most of the women tested had no family history of breast cancer and were unlikely to carry either the *BRCA1* or *BRCA2* mutation. Indeed, most of the tests were negative. The cost to the women was about \$3000 per test, but a more important cost may have been a false sense of security. Even in the absence of the *BRCA1* or *BRCA2* mutations, women have about a 12% lifetime risk of breast cancer.<sup>2</sup>

We have entered an era of personal genomics. Already, doctors can design medical treatments based on a patient's personal genome. For example, people with a certain genetic profile are less likely than others to benefit from statins, medications prescribed to lower cholesterol. Doctors are also choosing which cancer drugs to prescribe based on the unique genetic signatures of patients and their tumors. Although there is much left to decipher, it's clear that each of our individual genomes contains a wealth of biological information. As Gilmore says, "I've always been taught that knowledge is power."

# CHAPTER 12 DNA Replication and Manipulation

Andrea Danti/Shutterstock

## CORE CONCEPTS

**12.1 DNA REPLICATION:** In DNA replication, a single parental

molecule of DNA produces two daughter molecules.

**12.2 REPLICATION OF CHROMOSOMES:** The replication of linear chromosomal DNA requires mechanisms that ensure efficient and complete replication.

**12.3 DNA TECHNIQUES:** Techniques for manipulating DNA follow from the basics of DNA structure and replication.

**12.4 GENETIC ENGINEERING:** Genetic engineering allows researchers to alter DNA sequences in living organisms.

---

One of the overarching themes of biology is that the functional unit of life is the cell, a theme that rests, in turn, on the fundamental concept that all cells come from preexisting cells ([Chapter 1](#)). In [Chapter 11](#), we considered the mechanics of cell division and how it is regulated. Prokaryotic cells divide by binary fission, whereas eukaryotic cells divide by mitosis and cytokinesis. These processes ensure that cellular reproduction results in daughter cells that are like the parental cell. In other words, in cell division, like begets like. The molecular basis for the resemblance between parental cells and daughter cells is that a double-stranded DNA molecule in the parental cell duplicates and gives rise to two double-stranded daughter DNA molecules that are identical to each other, except for rare, uncorrected mutations that may have taken place.

The process of duplicating a DNA molecule is called [DNA replication](#), and it occurs in virtually the same way in all organisms, reflecting its evolution very early in life's history. The process is conceptually simple—the parental strands separate and new

complementary partner strands are made—but the molecular details are more complicated. Once scientists understood the molecular mechanisms of DNA replication, they could devise methods for manipulating and studying DNA. An understanding of DNA replication is therefore fundamental to understanding not only how cells and organisms produce offspring like themselves, but also some of the key experimental techniques in modern biology.

## 12.1 DNA REPLICATION

You may recall from [Chapter 3](#) that double-stranded DNA consists of a pair of deoxyribonucleotide polymers wound around each other in antiparallel helical coils in such a way that a purine base (A or G) in one strand is paired with a pyrimidine base (T or C, respectively) in the other strand. To say that the strands are antiparallel means that they run in opposite directions: one strand runs in the 5'-to-3' direction and the other runs in the 3'-to-5' direction. These key elements of DNA structure are the only essential pieces of information needed to understand the mechanism of DNA replication.

**During DNA replication, the parental strands separate and new partners are made.**

When Watson and Crick published their paper describing the structure of DNA, they also coyly laid claim to another discovery: “It has not escaped our notice that the specific pairing we have postulated [A with T, and G with C] immediately suggests a copying mechanism for the genetic material.” The copying mechanism they had in mind is exquisitely simple. The two strands of the parental duplex molecule separate ([Fig. 12.1](#)), and each individual parental strand serves as a model, or **template strand**, for the synthesis of a **daughter strand**. As each daughter strand is synthesized, the order of the bases in the template strand determines the order of the complementary bases added to the daughter strand. For example, the sequence 5'-ATGC-3' in the template strand specifies the sequence 3'-TACG-5' in the daughter

strand because A pairs with T and G pairs with C. (The designations 3' and 5' convey the antiparallel orientation of the strands.)

A key prediction of the model shown in [Fig. 12.1](#) is **semiconservative replication**. That is, after replication, each new DNA duplex consists of one strand that was originally part of the parental duplex and one newly synthesized strand. An alternative model is conservative replication, which proposes that the original DNA duplex remains intact and the daughter DNA duplex is completely new. Which model is correct? If there were a way to distinguish newly synthesized daughter DNA strands (“new strands”) from previously synthesized parental strands (“old strands”), the products of replication could be observed and the mode of replication determined.

American molecular biologists Matthew S. Meselson and Franklin W. Stahl carried out an experiment to determine how DNA replicates.

This experiment, described in [Fig. 12.2](#), has been called “the most beautiful experiment in biology” because it so elegantly demonstrates the process of generating hypotheses, making predictions, and performing an experiment to test the hypotheses ([Chapter 1](#)). Meselson and Stahl found that DNA replicates semiconservatively.

#### HOW DO WE KNOW?

### FIG. 12.2

## How is DNA replicated?

#### BACKGROUND

Watson and Crick’s discovery of the structure of DNA in 1953 suggested a mechanism by which DNA is replicated. Experimental evidence of how DNA is replicated came from research by American molecular biologists Matthew Meselson and Franklin Stahl in 1958.

#### HYPOTHESIS

DNA replicates in a semiconservative manner, meaning that each new DNA molecule consists of one parental strand and one newly synthesized strand.

#### ALTERNATIVE HYPOTHESIS

DNA replicates in a conservative manner, meaning that after replication, one DNA molecule consists of two parental strands and the other consists of two newly synthesized strands.

#### METHOD

Meselson and Stahl distinguished parental strands (“old strands”) from daughter strands (“new strands”) using two isotopes of nitrogen atoms. Old strands were labeled with a heavy form of nitrogen with an extra neutron ( $^{15}\text{N}$ ), and new strands were labeled with the normal, lighter form of nitrogen ( $^{14}\text{N}$ ).

## EXPERIMENT

The researchers first grew bacterial cells on medium containing only the heavy  $^{15}\text{N}$  form of nitrogen. As the cells grew,  $^{15}\text{N}$  was incorporated into the DNA bases, resulting, after several generations, in DNA containing only  $^{15}\text{N}$ . They then transferred the cells into medium containing only light  $^{14}\text{N}$  nitrogen. After one round of replication in this medium, cell replication was halted. The researchers could not observe the DNA directly, but they were able to measure the density of the DNA by spinning it in a high-speed centrifuge in tubes containing a solution of cesium chloride.

## PREDICTION

If DNA replicates conservatively, half of the DNA in the cells should be composed of two heavy parental strands containing  $^{15}\text{N}$ , and half should be composed of two light daughter strands containing  $^{14}\text{N}$ . If DNA replicates semiconservatively, after one round of replication, the daughter DNA molecules should each consist of one heavy strand and one light strand.

## RESULTS

When the fully  $^{15}\text{N}$ -labeled parental DNA was spun, it concentrated in a single heavy band with a density of  $1.722\text{ gm/cm}^3$  (Point 1 in the figure). This is the density of a duplex molecule containing two heavy ( $^{15}\text{N}$ -labeled) strands. After one round of replication, the DNA formed a band at a density of  $1.715\text{ gm/cm}^3$ , which is the density expected of a duplex molecule containing one heavy ( $^{15}\text{N}$ -labeled) strand and one light ( $^{14}\text{N}$ -labeled) strand (Point 2). DNA composed only of  $^{14}\text{N}$  has a density of  $1.708\text{ gm/cm}^3$ . After two rounds of replication, half the molecules exhibited a density of  $1.715\text{ gm/cm}^3$ , indicating a duplex molecule with one heavy strand and one light strand, and the other half exhibited a density of  $1.708\text{ gm/cm}^3$ , indicating a duplex molecule containing two light strands (Point 3).

## CONCLUSION

DNA replicates semiconservatively, supporting the first hypothesis.

SOURCE Meselson, M., and F. W. Stahl. 1958. "The Replication of DNA in *Escherichia coli*." *PNAS* 44:671–82.

Important as it was in demonstrating semiconservative replication in bacteria, the Meselson–Stahl experiment left open the possibility that DNA replication in eukaryotes might be different. It was only a few years after the Meselson–Stahl experiment that methods for labeling

DNA with fluorescent nucleotides were developed. These methods allowed researchers to visualize entire strands of eukaryotic DNA and follow each strand through replication.

**Fig. 12.3** shows a human chromosome with unlabeled DNA that subsequently underwent two rounds of replication in medium containing a fluorescent nucleotide. The chromosome was photographed at metaphase of the second round of mitosis, after chromosome duplication but before the separation of the chromatids into the daughter cells. Notice that one chromatid contains hybrid DNA with one labeled strand and one unlabeled strand, which fluoresces faintly (light); the other chromatid contains two strands of labeled DNA, which fluoresces strongly (dark). This result is conceptually the same as what was seen by Meselson and Stahl after two rounds of replication and exactly as predicted by the semiconservative replication model. The result also demonstrates that each eukaryotic chromosome contains a single DNA molecule that runs continuously all along its length.

## New DNA strands grow by the addition of nucleotides to the 3' end.

Although replication is semiconservative, this model alone does not tell us the details of replication. For example, the model implies that both daughter strands should grow in length by the addition of nucleotides near the site where the parental strands separate, a site called the **replication fork**. As more and more parental DNA is unwound and the replication fork moves forward (to the left in [Fig. 12.1](#)), both new strands would also grow in the direction of replication fork movement. However, it turns out that this scenario is impossible.

We have seen that the two DNA strands in a double helix run in an antiparallel fashion: one of the template strands (the strand that starts on the bottom in [Fig. 12.1](#)) has a left-to-right 5'-to-3' orientation, whereas the other template strand (the strand that starts on the top in [Fig. 12.1](#)) has a left-to-right 3'-to-5' orientation. Therefore, the new daughter strands also have opposite orientations so that near the replication fork, the daughter strand in the bottom duplex terminates in a 3' hydroxyl, whereas that in the top duplex terminates in a 5' phosphate. There's the rub: the strand that terminates in the 5' phosphate cannot grow in the direction of the replication fork because new DNA strands can grow only by the addition of successive nucleotides to the 3' end. That is, DNA always grows in the 5'-to-3' direction.

DNA polymerization occurs only in the 5'-to-3' direction because of the chemistry of nucleic acid synthesis, discussed in [Chapter 3](#). The building blocks of DNA ([Chapter 2](#)) are nucleotides, each consisting of a deoxyribose sugar with three phosphate groups attached to the 5' carbon (making them triphosphates), a nitrogenous base (A, T, G, or C) attached to the 1' carbon, and a free hydroxyl ( $-\text{OH}$ ) group attached to the 3' carbon. DNA polymerization occurs when the 3' hydroxyl at the growing end of the polynucleotide chain attacks the triphosphate group at the 5' end of an incoming nucleotide triphosphate ([Fig. 12.4](#)). As the incoming nucleotide triphosphate is added to the growing DNA strand, one of the nucleotide's high-energy phosphate bonds is broken to release the outermost two phosphates (called pyrophosphate), and immediately the high-energy phosphate bond in the pyrophosphate is cleaved to drive the polymerization reaction forward and make it irreversible.

FIG. 12.4 DNA synthesis by nucleotide addition to the 3' end of a growing DNA strand.

The polymerization reaction is catalyzed by **DNA polymerase**, an enzyme that is a critical component of a large protein complex that carries out DNA replication. DNA polymerases exist in all organisms and are highly conserved, meaning that they vary little from one species to another because they carry out an essential function. A cell typically contains several different DNA polymerase enzymes, each specialized for a particular situation. However, all DNA polymerases share the same basic function in that they synthesize a new DNA strand from an existing template. Most, but not all, also correct mistakes in replication, as we will see. DNA polymerases also have many practical applications in the laboratory, which we will discuss later in this

chapter.

## In replicating DNA, one daughter strand is synthesized continuously and the other in a series of short pieces.

Because a new DNA strand can be elongated only at the 3' end, the two daughter strands are synthesized in quite different ways ([Fig. 12.5](#)).

The daughter strand shown at the bottom of [Fig. 12.5](#) has its 3' end pointed toward the replication fork so that as the parental double helix unwinds, nucleotides can be added onto the 3' end, and this daughter strand can be synthesized as one long, continuous polymer. This daughter strand is called the **leading strand**.

FIG. 12.5 Leading and lagging strand synthesis. In DNA replication, because the

template strand is made of two antiparallel strands, one daughter strand (the leading strand) is synthesized continuously and the other daughter strand (the lagging strand) is synthesized in smaller pieces.

The situation is different for the daughter strand shown at the top in [Fig. 12.5](#). Its 5' end is pointed toward the replication fork, but the strand cannot grow in that direction. Instead, as the replication fork unwinds, it grows away from the fork and forms a stretch of single-stranded DNA of a few hundred to a few thousand nucleotides. Then, as the parental DNA duplex unwinds further, a new daughter strand is initiated with its 5' end near the replication fork, and this strand is elongated at the 3' end as usual. The result is that the daughter strand shown at the top in [Fig. 12.5](#) is actually synthesized in relatively short, discontinuous pieces. As the parental double helix unwinds, a new piece is initiated at intervals, and each new piece is elongated at its 3' end until it reaches the piece in front of it. This daughter strand is called the **lagging strand**. The short pieces in the lagging strand are sometimes called **Okazaki fragments** after their discoverer, Japanese molecular biologist Reiji Okazaki.

The presence of leading and lagging strands during DNA replication is a consequence of the antiparallel nature of the two strands in a DNA double helix and the fact that DNA polymerase can synthesize DNA in only one direction.

## A small stretch of RNA is needed to begin synthesis of a new DNA strand.

Each new DNA strand must begin with a short stretch of RNA that

serves as a **primer**, or starter, for DNA synthesis. The primer is needed because the DNA polymerase complex cannot begin a new strand on its own; it can only elongate the end of an existing piece of DNA or RNA. The primer is made by an RNA polymerase called **RNA primase**, which synthesizes a short piece of RNA complementary to the DNA template. Once the RNA primer has been synthesized, the DNA polymerase takes over and elongates the primer, adding successive DNA nucleotides to the 3' end of the growing strand.

Because the DNA polymerase complex extends an RNA primer, all new DNA strands have a short stretch of RNA at their 5' end. For the lagging strand, there are many such primers, one for each of the discontinuous fragments of newly synthesized DNA. As each of these fragments is elongated by DNA polymerase, it grows toward the primer of the fragment in front of it (**Fig. 12.6**). When the growing fragment comes into contact with the primer of the fragment synthesized earlier, a different DNA polymerase complex takes over, removing the earlier RNA primer and extending the growing fragment with DNA nucleotides to fill the space left by its removal. When the replacement is completed, the adjacent fragments are joined, or ligated, by an enzyme called **DNA ligase**.

FIG. 12.6 Synthesis and removal of RNA primers in the lagging strand.

## Synthesis of the leading and lagging strands is coordinated.

In addition to RNA primase and DNA ligase, many other enzymes play a role in DNA replication to ensure accurate and efficient synthesis of daughter strands. [Fig. 12.7a](#) shows enzymes that work at or near the replication fork. One of these, [topoisomerase II](#), works upstream from the replication fork to relieve the stress on the double helix that results

from its unwinding at the replication fork. In the meantime, [helicase](#) separates the strands of the parental double helix at the replication fork. Then, [single-strand binding protein](#) binds to these single-stranded regions to prevent the template strands from coming back together. These enzymes are evolutionarily conserved, and the process of replication is the same in all organisms. The two strands of the parental DNA duplex separate, and each serves as a template for the synthesis of a daughter strand according to the base-pairing rules of A–T and G–C, with each successive nucleotide being added to the 3' end of the growing strand.

Replication does not occur exactly as it is shown in [Fig. 12.7a](#). The DNA polymerase complexes for each strand stay in contact with each other so that synthesis of the leading and lagging strands is coordinated to occur at the same time and rate ([Fig. 12.7b](#)). In this arrangement, the lagging strand's polymerase releases and retrieves the lagging strand for the synthesis of each new RNA primer. The positioning of the polymerases is such that both the leading strand and the lagging strand pass through in the same direction, which requires that the lagging strand be looped around as shown in [Fig. 12.7b](#). In this configuration, the 3' end of the lagging strand and the 3' end of the leading strand are elongated together, which ensures that neither strand outpaces the other in its rate of synthesis.

As we discuss in [Chapter 14](#), when DNA damage occurs during replication, the rate of synthesis slows down so that the DNA can be repaired. If synthesis of one strand slows down to repair DNA damage, synthesis of the other strand slows down, too. The pairing of the replication complexes is disrupted when the RNA primer of the

previous Okazaki fragment is encountered, and then takes place again when a new lagging-strand primer is formed. The lagging-strand loop is sometimes called a “trombone loop.”

## DNA polymerase is self-correcting because of its proofreading function.

Most DNA polymerases can correct their own errors in a process called **proofreading**, which is a separate enzymatic activity from strand elongation (synthesis) (**Fig. 12.8**).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 12.8 Proofreading, the process by which an incorrect nucleotide is removed immediately after it is incorporated.

When each new nucleotide comes into line in preparation for attachment to the growing DNA strand, the nucleotide is temporarily

held in place by hydrogen bonds that form between the base in the new nucleotide and the base across the way in the template strand (see [Fig. 12.4](#)). The strand being synthesized and the template strand therefore have complementary bases—A paired with T, or G paired with C. However, on rare occasions, an incorrect nucleotide is attached to the new DNA strand. When this happens, DNA polymerase can correct the error because it detects mispairing between the template and the most recently added nucleotide. Mismatching between a base in the parental strand and a newly added base in the daughter strand activates a DNA-cleavage function of DNA polymerase that removes the incorrect nucleotide and inserts the correct one in its place.

Mutations resulting from errors in nucleotide incorporation still occur, but proofreading reduces their number. In the bacterium *E. coli*, for example, about 99% of the incorrect nucleotides that are incorporated during replication are removed and repaired by the proofreading function of DNA polymerase. Those that slip past proofreading and other repair systems lead to mutations, which are then faithfully copied and passed on to daughter cells. Some of these mutations may be harmful, but others are neutral and a rare few may be beneficial. These mutations are the ultimate source of genetic variation that we see among individuals of the same species and among species ([Chapter 14](#)).

#### Self-Assessment Questions

1. Suppose Meselson and Stahl had done their experiment ([Fig. 12.2](#)) the other way around, starting with cells fully labeled with  $^{14}\text{N}$  light DNA and then transferring them to medium containing

only  $^{15}\text{N}$  heavy DNA. What density of DNA molecule would you predict after one and two rounds of replication?

2. How does the structure of DNA itself suggest a mechanism of replication?
3. How does the chemical structure of deoxynucleotides determine the orientation of the DNA strands, and how does this affect the direction of DNA synthesis?
4. What are the differences and similarities in the way the two daughter strands of DNA are synthesized at a replication fork?

## 12.2 REPLICATION OF CHROMOSOMES

The basic steps involved in semiconservative DNA replication are universal, suggesting that they evolved in the common ancestor of all living organisms. In addition, they are the same whether they occur in a test tube or in a cell, or whether the segment of DNA being replicated is short or long. However, the replication of an entire linear chromosome poses particular challenges. Here, we consider two such challenges encountered by cells in replicating their chromosomes: how replication starts and how it ends.

### Replication of DNA in chromosomes starts at many places almost simultaneously.

DNA replication is relatively slow. In eukaryotes, it occurs at a rate of about 50 nucleotides per second. At this rate, replication from end to end of the DNA molecule in the largest human chromosome would take almost two months. In fact, it takes only a few hours. This fast pace is possible because in a long DNA molecule, replication begins almost simultaneously at many places. Each point at which DNA synthesis is initiated is called an **origin of replication**. The opening of the double helix at each origin of replication forms a **replication bubble** with a replication fork on each side, each with a leading strand and a lagging strand with topoisomerase II, helicase, and single-strand binding protein playing their respective roles (**Fig. 12.9**). DNA synthesis takes place at each replication fork, and as the replication

forks move in opposite directions, the replication bubble increases in size. When two replication bubbles meet, they fuse to form one larger replication bubble.

Note in [Fig. 12.9](#) that within a single replication bubble, the same daughter strand is the leading strand at one replication fork and the lagging strand at the other replication fork. This situation results from the fact that the replication forks in each replication bubble move away from each other. When two replication bubbles fuse and the leading strand from one meets the lagging strand from the other, the ends of the

strands that meet are joined by DNA ligase, just as happens when the discontinuous fragments within the lagging strand meet (see [Fig. 12.6](#)).

Some DNA molecules, including most of the DNA molecules in bacterial cells and the DNA in mitochondria and chloroplasts ([Chapter 3](#)) are small circles, not long linear molecules. Such circular DNA molecules typically have only one origin of replication ([Fig. 12.10](#)). Replication takes place at both replication forks, and the replication forks proceed in opposite directions around the circle until they meet and fuse on the opposite side, completing one round of replication.

## Telomerase restores tips of linear chromosomes shortened during DNA replication.

A circular DNA molecule can be replicated completely because it has no ends, and the replication forks can move completely around the

circle ([Fig. 12.10](#)). Linear DNA molecules have ends, however, and at each round of DNA replication, the ends become slightly shorter. The reason for the shortening is illustrated in [Fig. 12.11](#).

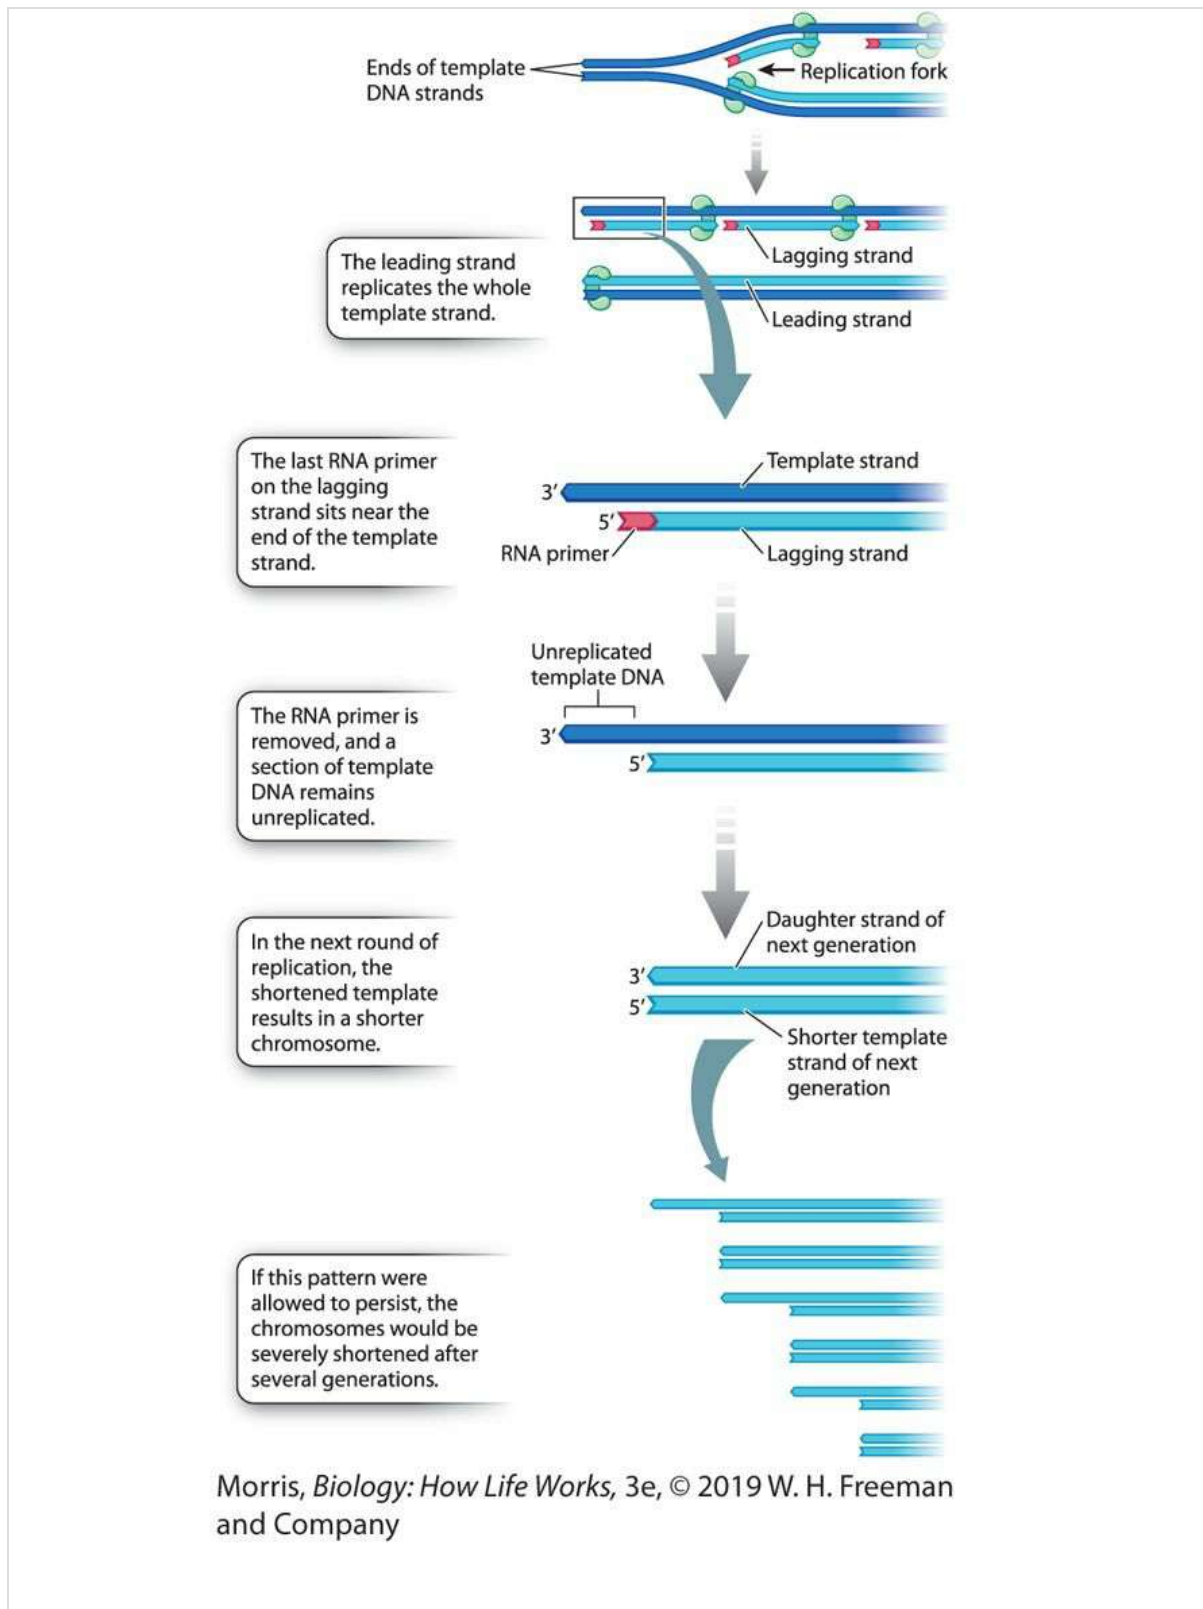

FIG. 12.11 Shortening of linear DNA at the ends. Because an RNA primer cannot be synthesized precisely at the 3' end of a DNA strand, its partner strand becomes a little shorter in each round of replication.

Recall that each fragment of newly synthesized DNA starts with an RNA primer. On the leading strand, the only primer required is at the origin of replication when synthesis begins. The leading strand is elongated in the same direction as the moving replication fork and is able to replicate the template strand all the way to the end. On the lagging strand, however, which grows away from the replication fork, many primers are required, and the final RNA primer is synthesized about 100 nucleotides from the 3' end of the template. Because this primer initiates synthesis of the final Okazaki fragment of the lagging strand, no other Okazaki fragment is available to synthesize the missing 100 base pairs and remove the primer. Therefore, when DNA replication is complete, the new daughter DNA strand (light blue in [Fig. 12.11](#)) will be missing about 100 base pairs from the tip (plus a few more owing to the length of the primer). When this new daughter strand is replicated, the newly synthesized strand must terminate at the shortened end of the template strand, and so the new duplex molecule is shortened by about 100 base pairs from the original parental molecule. The strand shortening in each round of DNA replication is a problem because without some mechanism to restore the tips, the DNA in the chromosome would eventually be nibbled away to nothing.

Eukaryotic organisms have evolved mechanisms that solve the problem of shortened ends ([Fig. 12.12](#)). Each end of a eukaryotic chromosome is capped by a repeating sequence called the **telomere**.

The repeating sequence that constitutes the telomere differs from one group of organisms to the next, but in the chromosomes of humans and other vertebrates, it consists of the sequence 3'-GGGATT-5' repeated over and over again in about 1500–3000 copies. For simplicity, just four copies of this telomere sequence are shown in [Fig. 12.12](#). The telomere is slightly shortened in each round of DNA replication, as shown in [Fig. 12.11](#), but the shortened end is quickly restored by an enzyme known as **telomerase**, which contains an RNA molecule complementary to the telomere sequence.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 12.12 Telomerase. Telomerase prevents successive shortening of linear chromosomes.

As shown in [Fig. 12.12](#), the telomerase replaces the lost telomere repeats by using its RNA molecule as a guide to add successive DNA nucleotides to the 3' end of the template strand. Once the 3' end of the

template strand has been elongated, an RNA primer and the complementary DNA strand are synthesized. In this way, the original telomere is completely restored. Because no genes are present in the telomere, the slight shortening and subsequent restoration that take place have no harmful consequences.

Telomerase activity differs from one cell type to the next. It is fully active in **germ cells**, which produce sperm or eggs, and also in **stem cells**, which are undifferentiated cells that can undergo an unlimited number of mitotic divisions and can differentiate into any of a large number of specialized cell types. Stem cells are found in embryos, where they differentiate into all the various cell types of the body. Stem cells are also found in some tissues of the body after embryonic development, where they replenish cells that have a high rate of turnover, such as blood and intestinal cells, and play a role in tissue repair.

In contrast to the high activity of telomerase in germ cells and stem cells, telomerase is almost inactive in most cells in the adult body. In these cells, the telomeres are actually shortened by about 100 base pairs in each mitotic division. Telomere shortening limits the number of mitotic divisions that the cells can undergo because human cells stop dividing when their chromosomes have telomeres with fewer than about 100 copies of the telomere repeat. Adult somatic cells can therefore undergo only about 50 mitotic divisions until the telomeres are so short that the cells stop dividing.

Many biologists believe that the limit on the number of cell

divisions explains, in part, why our tissues become less youthful and wounds heal more slowly with age. The telomere hypothesis of aging is still controversial, but increasing evidence suggests that it is one of several factors that lead to aging. The flip side of the coin is observed in cancer cells, in which telomerase is reactivated and helps support the uncontrolled growth and division of abnormal cells.

#### Self-Assessment Questions

5. Why is replicating the ends of linear chromosomes problematic?
6. How does the cell overcome the challenge of replicating chromosome ends?

## 12.3 DNA TECHNIQUES

Watson and Crick's discovery of the structure of DNA and knowledge of the mechanism of replication allowed biologists not only to understand some of life's central processes, but also to create tools to study how life works. Biologists often need to isolate, identify, and determine the nucleotide sequence of particular DNA fragments. Such procedures can determine whether a genetic risk factor for diabetes has been inherited, blood at a crime scene matches that of a suspect, a variety of rice or wheat carries a genetic factor for insect resistance, or two species of organisms are closely related. Many of the experimental procedures for the isolation, identification, and sequencing of DNA are based on knowledge of DNA structure and physical properties of DNA. Others make use of the principles of DNA replication.

In this section, we discuss how particular fragments of double-stranded DNA can be produced, how DNA fragments of different sizes can be physically separated, and how the nucleotide sequence of a piece of DNA can be determined.

### The polymerase chain reaction selectively amplifies regions of DNA.

DNA that exists in the nuclei of your cells is present in two copies per cell, except for DNA in the *X* and *Y* chromosomes in males, which are each present in only one copy per cell. In the laboratory, it is very difficult to manipulate or visualize a sample containing just one or two copies of a DNA molecule. Instead, researchers typically work with many identical copies of the DNA molecule they are interested in

studying. A common method for making copies of a piece of DNA is the [polymerase chain reaction \(PCR\)](#), which allows a targeted region of a DNA molecule to be replicated (or [amplified](#)) into as many copies as desired. PCR is both selective and highly sensitive, so it is used to amplify and detect small quantities of nucleic acids, such as HIV in blood-bank supplies, or to study DNA samples as minuscule as those left by a smoker's lips on a cigarette butt dropped at the scene of a crime. The starting sample can be as small as a single molecule of DNA.

The principles of PCR are illustrated in [Fig. 12.13](#). Because the PCR reaction is essentially a DNA synthesis reaction, it requires the same basic components used by the cell to replicate its DNA. In this case, the procedure takes place in a small plastic tube containing a solution that includes four essential components:

1. Template DNA. At least one molecule of double-stranded DNA containing the region to be amplified serves as the template for amplification.
2. DNA polymerase. The enzyme DNA polymerase is used to replicate the DNA.
3. All four deoxynucleoside triphosphates. Deoxynucleoside triphosphates with the bases A, T, G, or C are needed as building blocks for the synthesis of new DNA strands.
4. Two primers. Two short sequences of single-stranded DNA are required for the DNA polymerase to start synthesis. Enough primer is added so that the number of primer DNA molecules is much greater than the number of template DNA molecules.

FIG. 12.13 The polymerase chain reaction (PCR). PCR results in amplification of the DNA sequence flanked by the two primers.

The primer sequences are **oligonucleotides** (*oligos* is the Greek word for “few”) produced by chemical synthesis and are typically 20–30 nucleotides long. Their base sequences are chosen to be complementary to the ends of the region of DNA to be amplified. In

other words, the primers flank the specific region of DNA to be amplified. The 3' end of each primer must be oriented toward the region to be amplified so that, when DNA polymerase extends the primer, it creates a new DNA strand complementary to the targeted region. Because the 3' ends of the primers both point toward the targeted region, one of the primers pairs with one strand of the template DNA and the other pairs with the other strand of the template DNA.

PCR creates new DNA fragments in a cycle of three steps, as shown in [Fig. 12.13a](#). The first step, **denaturation**, involves heating the solution in a plastic tube to a temperature just short of boiling so that the individual DNA strands of the template separate (or “denature”) as a result of the breaking of hydrogen bonds between the complementary bases. The second step, **annealing**, begins as the solution is cooled. Because of the great excess of primer molecules, the two primers bind (or “anneal”) to their complementary sequence on the DNA (rather than two strands of the template duplex coming back together). In the final step, **extension**, the solution is heated to the optimal temperature for DNA polymerase and the polymerase elongates (or “extends”) each primer with the deoxynucleoside triphosphates.

After sufficient time to allow new DNA synthesis, the solution is heated again, and the cycle of denaturation, annealing, and extension is repeated over and over, as indicated in [Fig. 12.13b](#), usually for 25–35 cycles. In each cycle, the number of copies of the targeted fragment is doubled. The first round of PCR amplifies the targeted region into 2 copies, the next into 4, the next into 8, then 16, 32, 64, 128, 256, 512,

1024, and so forth. By the third round of amplification, the process begins to produce molecules that are only as long as the region of the template duplex flanked by the sequences complementary to the primers. After several more rounds of replication, the majority of molecules are of this type. The doubling in the number of amplified fragments in each cycle justifies the term “chain reaction.”

Although PCR is elegant in its simplicity, the DNA polymerase enzymes from many species (including humans) irreversibly lose both structure and function at the high temperature required to separate the DNA strands. At each cycle, you would have to open the tube and add fresh DNA polymerase. This is possible, and, in fact, it was how PCR was performed when the technique was first developed, but the procedure is time-consuming and tedious. To solve this problem, we now use DNA polymerase enzymes that are heat-stable, such as those from the bacterial species *Thermus aquaticus*, which lives at the near-boiling point of water in natural hot springs, including those at Yellowstone National Park. This polymerase, called *Taq* polymerase, remains active at high temperatures. Once the reaction mixtures are set up, the entire procedure is carried out in a fully automated machine. The time of each cycle, temperatures, number of cycles, and other variables can all be programmed. The fact that DNA polymerase from a bacterium that lives in hot springs can be used to amplify DNA from any organism reminds us again of the conserved function and evolution of this enzyme early in the history of life.

## Electrophoresis separates DNA fragments by size.

PCR amplification does not always work as you might expect. Sometimes the primers have the wrong sequence and thus fail to anneal properly; sometimes they anneal to multiple sites and several different fragments are amplified. To determine whether or not PCR has yielded the expected product, a researcher must determine the size of the amplified DNA molecules. Usually, the researcher knows what the size of the correctly amplified fragment should be, making it possible to compare the expected size to the actual size.

One way to determine the size of a DNA fragment is by **gel electrophoresis** ([Fig. 12.14](#)), a procedure in which DNA fragments are separated by size as they migrate through a porous substance in response to an electrical field. In this procedure, DNA samples are first inserted into slots or wells near the edge of a rectangular slab of porous material that resembles solidified agar (the “gel”). The porous nature of the gel is due to its composition of a tangle of polymers. This tangle of polymers makes it difficult for large molecules to pass through. The gel is then inserted into an apparatus and immersed in a solution that allows an electric current to be passed through it, from negative at the top of the gel where the DNA samples are initially placed, to positive at the bottom of the gel ([Fig. 12.14a](#)). This electrical field is what causes the DNA to migrate through the porous gel. Fragments of double-stranded DNA in this solution are negatively charged because of the ionized (negative) phosphate groups along the backbone in the solution. Therefore, the DNA molecules move toward the positive pole of the electric field.

FIG. 12.14 Gel electrophoresis. (a) A typical electrophoresis apparatus consists of a plastic tray, gel, and solution. (b) DNA bands can be visualized after staining with a dye that fluoresces under ultraviolet light.

The DNA molecules move according to their size. Short fragments pass through the pores of the gel more readily than large fragments, and so in a given interval of time, short fragments move a greater distance in the gel than large fragments. The rate of migration is dependent only on size, not on sequence, and so all fragments of a given size move together at the same rate in a discrete band, which can be made visible by dyes that bind to DNA and fluoresce under ultraviolet light ([Fig. 12.14b](#)). A solution of DNA fragments of known sizes is usually placed in one of the wells, resulting in a series of bands, called a ladder, which can be used for size comparison.

Consider a PCR experiment with 25 base-pair (bp) primers flanking a 250-bp length of DNA. PCR amplifies this region, generating many millions of copies of a 300-bp DNA fragment consisting of the 250-bp

target sequence and the primer sequences on both ends. To determine if the PCR experiment worked as expected, a sample of the product is checked by gel electrophoresis. This sample is loaded into the well of the gel, a current is applied for a short period of time, and DNA fragments migrate to positions in the gel that correspond to their size, creating bands of DNA that are visualized with a dye. If a single band of 300 bp is seen on the gel, then the experiment worked as expected. Sometimes, however, the reaction might yield no bands, a single band of the incorrect size, or multiple bands. The researcher would then need to go back and investigate why the experiment did not work as expected.

Gel electrophoresis can separate DNA fragments produced by any means, not only PCR. Genomic DNA can be cut with certain enzymes and the resulting fragments separated by gel electrophoresis, as described in the next section. Similar procedures can also be used to separate protein molecules.

## Restriction enzymes cleave DNA at particular short sequences.

In addition to amplifying segments of DNA, researchers often also make use of techniques that cut DNA at specific sites. Cutting DNA molecules allows pieces from the same or different organisms to be brought together in recombinant DNA technology, which is discussed in [section 12.4](#). It also is a way to determine whether or not specific sequences are present in a segment of DNA, because techniques for cutting DNA depend on specific DNA sequences. Finally, cutting DNA allows whole genomes to be broken into smaller pieces for

further analysis, such as DNA sequencing.

The method for cutting DNA makes use of enzymes that recognize specific, short nucleotide sequences in double-stranded DNA and cleave the DNA at these sites. These enzymes are known as [restriction enzymes](#). There are about 1000 different kinds of restriction enzymes isolated from bacteria and other microorganisms, but they cut DNA from any organism whatsoever. The recognition sequences that the enzymes cleave, called [restriction sites](#), are typically four or six base pairs long. Most restriction enzymes cleave double-stranded DNA at or near the restriction site. For example, the enzyme *EcoRI* recognizes the following restriction site:

Wherever the enzyme finds this site in a DNA molecule, it cleaves each strand exactly at the position indicated by the vertical arrows. Note that the *EcoRI* restriction site is symmetrical: reading from the 5' end to the 3' end, the sequence of the top strand is exactly the same as the sequence of the bottom strand. This kind of symmetry is [palindromic](#) (it reads the same in both directions) and is typical of restriction sites. Note also that the site of cleavage is not in the center of the recognition sequence. The cleaved double-stranded molecules, therefore, each terminate in a short single-stranded overhang. In this case, the overhang is at the 5' end, as shown below:

[Table 12.1](#) shows more examples of restriction enzymes. Some cleave their restriction site to produce a 5' overhang, others produce a 3' overhang, and still others cleave in the middle of their restriction site and leave blunt ends with no overhang. The standard symbols for restriction enzymes include both italic and roman letters. The italic letters stand for the species from which the enzyme is derived (*E. coli* in the case of *EcoRI*, *Bacillus amyloliquefaciens* in the case of *BamHI*), and the Roman letters designate the particular restriction enzyme isolated from that species.

TABLE 12.1 Examples of Restriction Enzymes with Six-Base Cleavage Sites

When a particular restriction enzyme is used to break up a whole genome into smaller fragments, the specificity of restriction enzymes ensures that the DNA from each cell in an individual organism yields the same set of fragments and any particular DNA sequence present in

the cells is contained in a fragment of the same size. If the genome is small enough that the number and sizes of the fragments are limited, the individual fragments can be visualized directly in a gel ([Fig. 12.15](#)). These fragments can then be extracted from the gel for further analysis or manipulation. For instance, the extracted fragments can be sequenced or ligated to other fragments.

FIG. 12.15 *EcoRI* restriction fragments (a) on a circular DNA plasmid and (b) separated on a gel.

However, most genomes are too large to give such a simple picture. For example, the human genome is cleaved into more than a million different fragments by *EcoRI*, and these fragments appear as one big smear in a gel rather than as a series of discrete bands. In the next section, we discuss how individual bands containing a sequence of interest can be detected in such a gel.

## DNA strands can be separated and brought back together again.

A researcher may wish to know whether a gene in one species is

present in the DNA of a related species, but the nucleotide sequence of the gene is unknown. In such a case, techniques like PCR that require knowledge of the target DNA sequence cannot be used. Instead, the researcher can determine whether a DNA strand that contains the gene in one species can base pair with the complement of a similar gene in a DNA strand from the other species. The base pairing of complementary single-stranded nucleic acids is known as [renaturation](#) or hybridization, and the process is the opposite of denaturation. In denaturation, the DNA strands in a duplex molecule are separated, and in renaturation, complementary strands come together again. Denaturation and renaturation are also opposites in regard to the experimental conditions in which they occur. When a solution containing DNA molecules is gradually heated to a sufficiently high temperature, the strands denature. When the solution is allowed to cool, the complementary strands renature.

Denatured DNA strands from one source can renature with DNA strands from a different source if their sequences are precisely or mostly complementary. Two very closely related sequences will have more perfectly matched bases and thus more hydrogen bonds holding them together than two sequences that are less closely related. The amount of base pairing between two sequences affects the temperature at which they renature: very closely related sequences renature at a higher temperature than less closely related sequences. Evolutionary biologists have used this principle to estimate the proportion of perfectly matched bases present in the DNA of different species, which is used as a measure of how closely those species are related ([Chapter 22](#)). In general, the more closely two species are related, the more

similar their DNA sequences. Knowledge of species relatedness is important in many applications, including conservation, identifying endangered species, and tracing the evolutionary history of organisms.

Renaturation makes it possible to use a small DNA fragment as a **probe**. This fragment is usually attached to a light-emitting or radioactive chemical that serves as a label. The probe can be used to determine whether or not a sample of double-stranded DNA molecules contains sequences that are complementary to it. Any DNA fragment can be used as a probe, and a probe can be obtained in any number of ways, such as by chemical isolation of a DNA fragment, amplification by PCR, or synthesizing a nucleic acid from free nucleotides.

Let's say you are interested in determining the number of copies of a particular DNA sequence in a genome or determining whether a given gene in human genomic DNA is intact. Recall that human and other genomic DNA cut with a restriction enzyme yield a large number of DNA fragments that look like a smear on a gel after electrophoresis. A labeled probe can be used to determine the size and number of a DNA sequence of interest in a gel. The method is known as a **Southern blot** (**Fig. 12.16**) after its inventor, the British molecular biologist Edwin M. Southern.

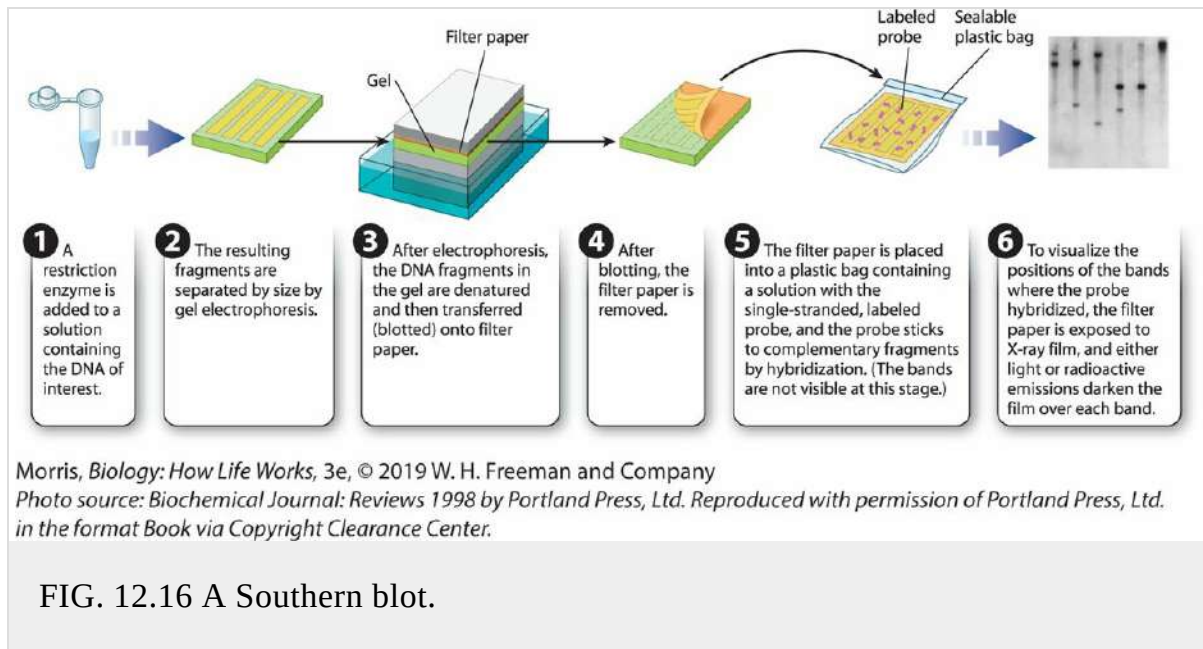

FIG. 12.16 A Southern blot.

In a Southern blot, single-stranded DNA molecules that have migrated to bands on a gel are transferred to a filter paper, such that they are on the same spot on the paper as they were on the gel. The filter paper is washed with a solution containing single-stranded probes that hybridize to whichever pieces of DNA on the filter paper are complementary. The paper is then exposed to X-ray film (in the case of radioactively labeled probes) so the bands can be visualized.

The presence of a band or bands on the film, therefore, indicates the number and size of DNA fragments that are complementary to the probe. This information, in turn, tells you the sizes and the number of copies of a particular DNA sequence present in the starting sample.

## DNA sequencing makes use of the principles of DNA replication.

The ability to determine the nucleotide sequence of DNA molecules has given a tremendous boost to biological research. Techniques used

to sequence DNA follow from our understanding of DNA replication. Consider a solution containing identical single-stranded molecules of DNA, each being used as the template for the synthesis of a complementary daughter strand that originates at a short primer sequence. The problem is to determine the nucleotide sequence of the template strand. A brilliant answer to this problem was developed by the English geneticist Frederick Sanger, an achievement rewarded with a share in the Nobel Prize in Chemistry in 1980. (It was his second Nobel; he had also been honored with the award in 1958 for his discovery of a method for determining the sequence of amino acids in a polypeptide chain.)

Recall that a free 3' hydroxyl group is essential for each step in elongation because that is where the incoming nucleotide is attached ([Fig. 12.17a](#)). Making use of this fact, Sanger synthesized [dideoxynucleotides](#), in which the 3' hydroxyl group on the sugar ring is absent ([Fig. 12.17b](#)). Whenever a dideoxynucleotide is incorporated into a growing daughter strand, there is no hydroxyl group to attack the incoming nucleotide, and strand growth is stopped dead in its tracks ([Fig. 12.18a](#)). For this reason, a dideoxynucleotide is known as a [chain terminator](#). By including a small amount of each of the chain terminators (A, G, C, and T) in a reaction tube along with larger quantities of all four normal nucleotides, a DNA primer, a DNA template, and DNA polymerase, Sanger was able to produce a series of interrupted daughter strands, each terminating at the site at which a dideoxynucleotide was incorporated.

**Fig. 12.18b** shows how the interrupted daughter strands help us to determine the DNA sequence by the procedure now called **Sanger sequencing**. In a tube containing dideoxy-A and all the other elements required for many rounds of DNA replication, a strand of DNA is synthesized complementary to the template until, when it reaches a T in the template strand, it incorporates an A. Only a small fraction of the A nucleotides in the sequencing reaction is in the dideoxy form, so only a fraction of the daughter strands incorporates a dideoxy-A at that point, resulting in termination. The rest of the strands incorporate a normal deoxy-A and continue synthesis, although most of these will be stopped at some point farther along the line when a T is reached again. Similarly, in a reaction containing dideoxy-C, DNA fragments will be

produced whose sizes correspond to the positions of the Cs, and likewise for dideoxy-T and dideoxy-G.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 12.18 Sanger sequencing. (a) The incorporation of an incoming

dideoxynucleotide stops the elongation of a new strand. (b) Dideoxynucleotides terminate strands at different points in the template sequence. (c) Separation of interrupted daughter strands by size shows where each terminator was incorporated and hence the identity of the corresponding nucleotide in the template strand.

Each of the four dideoxynucleotides is chemically labeled with a different fluorescent dye, as indicated by the different colors of A, C, T, and G in [Fig. 12.18b](#), and so all four terminators can be present in a single reaction and still be distinguished. After DNA synthesis is complete, the daughter strands are separated by size with gel electrophoresis. The smallest daughter molecules migrate most quickly and, therefore, are the first to reach the bottom of the gel, followed by the others in order of increasing size. A fluorescence detector at the bottom of the gel “reads” the colors of the fragments as they exit the gel. What the scientist sees is a trace (or graph) of the fluorescence intensities, such as the one shown in [Fig. 12.18c](#). The differently colored peaks, from left to right, represent the order of fluorescently tagged DNA fragments emerging from the gel. Thus, a trace showing peaks colored green-purple-red-green-purple-purple-blue-green-blue-red corresponds to a daughter strand having the sequence 5'-ACTACCGAGT-3' ([Fig. 12.18c](#)). In the Sanger sequencing method, each sequencing reaction can determine the sequence of about 1000 nucleotides in the template DNA molecule.

### CASE 3 YOUR PERSONAL GENOME: YOU, FROM A TO

T

# What new technologies are used to sequence your personal genome?

One of the high points of modern biology has been the determination of the complete nucleotide sequence of the DNA in a large number of species, including ours. The human genome and many others were sequenced by Sanger sequencing. This technique works well and is still the gold standard for accuracy, but it takes time and is expensive for large genomes like the human genome. Since it was first put into practice, Sanger sequencing has undergone many improvements, including the use of four-color fluorescent dyes to label the DNA fragments, capillary electrophoresis to separate the fragments, photoreceptors to read the fluorescent signals automatically as the products run off the gel, and highly efficient enzymes. Together, these methods have increased the speed and decreased the cost of DNA sequencing considerably.

However, the ability to sequence everyone's genome, including yours, will require new technologies to further reduce the cost and increase the speed of sequencing. The first human genome sequence, completed in 2003 at a cost of approximately \$2.7 billion, stimulated great interest in large-scale sequencing and the development of devices that increased scale and decreased cost. As in the development of computer hardware, emphasis was on making the sequencing devices smaller while increasing their capacity through automation.

Modern methods of sequencing include the use of fluorescent nucleotides or light-detection devices that reveal the identity of each base as it is added to the growing end of a DNA strand. Another

approach passes individual DNA molecules through a pore in a charged membrane; as each nucleotide passes through the pore, it is identified by means of the tiny difference in charge that occurs. These miniaturized and automated devices carry out what is often called massively parallel sequencing, which can determine the sequence of hundreds of millions of base pairs in a few hours.

The goal of technology development was captured in the catchphrase “the \$1000 genome,” a largely symbolic target indicating a reduction in sequencing cost from about \$1 million per megabase to less than \$1 per megabase. For all practical purposes, the \$1000-genome target has been achieved, but \$1000 is still too costly to make genome sequencing a routine diagnostic procedure. The technologies are still evolving and the costs decreasing, and so it is a fair bet that in the coming years, your own personal genome can be sequenced quickly and cheaply.

#### Self-Assessment Questions

7. You have determined that the newly synthesized strand of DNA in your sequencing reaction has the sequence 5'-ACTACCGAGT-3'. What is the sequence of the template strand?
8. What does PCR do? Name and explain its three steps, and describe at least two uses for the PCR technique.
9. How do the properties of DNA determine how it moves through a gel, is cut by restriction enzymes, and hybridizes to other DNA strands?
10. How are DNA molecules sequenced?

## 12.4 GENETIC ENGINEERING

Along with methods to manipulate DNA fragments, the capability to isolate genes from one species and introduce them into another also emerged. This type of genetic engineering is called recombinant DNA technology because it literally recombines DNA molecules from two (or more) different sources into a single molecule. Recombinant DNA technology involves cutting DNA by restriction enzymes, isolating the resulting DNA fragments by gel electrophoresis, and ligating the fragments with enzymes used in DNA replication. This technology is possible because the DNA of all organisms is the same, differing only in sequence and not in chemical or physical structure. When DNA fragments from different sources are combined into a single molecule and incorporated into a cell, they are replicated and transcribed just like any other DNA molecule.

Recombinant DNA technology can combine DNA from any two sources, including different species. DNA from one species of bacteria can be combined with another, or a human gene can be combined with bacterial DNA, or the DNA from a plant and a fungus can be combined into a single molecule. These new sequences may be unlike any found in nature, raising questions about their possible effects on human health and the environment.

This section discusses one of the basic methods for producing recombinant DNA, some of the important applications of recombinant DNA technology such as genetically modified organisms, and a new method that can be used to change the DNA sequence of any organism into any other desired sequence.

# Recombinant DNA combines DNA molecules from two or more sources.

The first application of recombinant DNA technology was the introduction of foreign DNA fragments into the cells of bacteria in the early 1970s. The method is simple and straightforward, and remains one of the mainstays of modern molecular research. It can be used to generate a large quantity of a protein for study or therapeutic use.

The method requires a fragment of double-stranded DNA that serves as the donor. The donor fragment may be a protein-coding gene, a regulatory part of a gene, or any DNA segment of interest. If you are interested in generating bacteria that could produce human insulin, you might use the coding region of the human insulin gene as your donor DNA molecule. Many genes in humans and other eukaryotes are very long—in some cases, more than a million base pairs. The messenger RNA from such long protein-coding genes is often much shorter than the gene itself because much of the primary transcript is composed of introns that are removed during RNA splicing ([Chapter 3](#)). To obtain a DNA fragment that contains only the protein-coding region of the gene, researchers make use of reverse transcriptase, which is an enzyme that produces a double-stranded DNA molecule from a single-stranded RNA template. For example, researchers can start with insulin mRNA, add reverse transcriptase, and obtain a DNA molecule that can be used as the donor. A DNA molecule produced with reverse transcriptase is known as [complementary DNA \(cDNA\)](#). Reverse transcriptase is discussed further in [Chapter 13](#).

Once a molecule of donor DNA has been isolated, another

requirement for recombinant DNA is a [vector](#) sequence into which the donor fragment is inserted. The vector is the carrier of the donor fragment, and it must have the ability to be maintained in bacterial cells. A frequently used vector is a bacterial [plasmid](#), a small circular molecule of DNA found naturally in certain bacteria that can replicate when the bacterial genomic DNA replicates and be transmitted to the daughter bacterial cells when the parental cell divides. Many naturally occurring plasmids have been modified by genetic engineering to make them suitable for use as vectors in recombinant DNA technology.

A common method for producing recombinant DNA is shown in [Fig. 12.19](#). In order to make sure donor DNA can be fused with vector DNA, both pieces are cut with the same restriction enzyme so they both have the same overhangs. In the example shown in [Fig. 12.19](#), the donor DNA is a fragment produced by digestion of genomic DNA with the restriction enzyme *EcoRI*, resulting in four-nucleotide 5' overhangs at the fragment ends. The vector is a circular plasmid that contains a single *EcoRI* cleavage site, so digestion of the vector with *EcoRI* opens the circle with a single cut that also has four-nucleotide 5' overhangs. Note that the overhangs on the donor fragment and the vector are complementary, allowing the ends of the donor fragment to renature with the ends of the opened vector when the two molecules are mixed. Once this renaturation has taken place, the ends of the donor fragment and the vector are covalently joined by DNA ligase. The joining of the donor DNA to the vector creates the recombinant DNA molecule.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 12.19 Recombinant DNA. Donor DNA fragments are joined with a vector molecule that can replicate in bacterial cells.

The next step in the procedure is **transformation**, in which the recombinant DNA is mixed with bacteria that have been chemically coaxed into a physiological state in which they take up DNA from outside the cell. Having taken up the recombinant DNA, the bacterial cells are transferred into growth medium, where they multiply. Because the vector part of the recombinant DNA molecule contains all the DNA sequences needed for its replication and partition into the daughter cells, the recombinant DNA multiplies as the bacterial cell multiplies. If the recombinant DNA functions inside the bacterial cell, then new genetic characteristics may be expressed by the bacteria. For example, the recombinant DNA may allow the bacterial cells to produce a human protein, such as insulin or growth hormone.

## Recombinant DNA is the basis of genetically modified organisms.

Applications of recombinant DNA have gone far beyond genetically engineered bacteria. Using methods that are conceptually similar to those described for bacteria but differing in many details, scientists have been able to produce varieties of genetically engineered viruses and bacteria, laboratory organisms, agricultural crops, and domesticated animals (**Fig. 12.20**). Examples include sheep that produce a human protein in their milk that is used to treat emphysema, chickens that produce eggs containing human antibodies to help fight harmful bacteria, and salmon with increased growth hormone for rapid

growth. Plants such as corn, canola, cotton, and many others have been engineered to resist insect pests. Additional engineered products include rice with a high content of vitamin A, tomatoes with delayed fruit softening, potatoes with waxy starch, and sugarcane with increased sugar content. To model disease, researchers have used recombinant DNA to produce organisms such as laboratory mice that have been engineered to develop heart disease and diabetes. By studying these organisms, researchers can better understand human diseases and begin to find new treatments for them.

FIG. 12.20 Genetically modified organisms (GMOs). Organisms can be genetically modified so that (a) wheat resists weed-killing herbicides, (b) soybeans resist insects and have improved oil quality, (c) sheep produce more healthy fats,

(d) chickens are unable to spread bird flu, (e) salmon have faster growth, and (f) pigs digest plant phosphorus more efficiently.

Genetically engineered organisms are known as **transgenic organisms** or **genetically modified organisms (GMOs)**. Transgenic laboratory organisms are indispensable in the study of gene function and regulation and for the identification of genetic risk factors for disease. In crop plants and domesticated animals, GMOs promise enhanced resistance to disease, faster growth and higher yields, more efficient utilization of fertilizer or nutrients, and improved taste and quality. However, there are concerns about unexpected effects on human health or the environment, the increasing power and influence of agribusiness conglomerates, and ethical objections to tampering with the genetic makeup of animals and plants. Nevertheless, more than 250 million acres of GMO crops are grown annually in more than 20 countries. The majority of this acreage is in the United States and South America. Resistance to the use of GMOs in Europe remains strong and vocal.

## DNA editing can be used to alter gene sequences almost at will.

Recombinant DNA technology combines existing DNA from two or more different sources. Its usefulness in research, medicine, and agriculture, however, is limited by the fact that it can make use only of existing DNA sequences. Therefore, scientists have also developed many different techniques to alter the nucleotide sequence of almost any gene in a deliberate, targeted fashion. In essence, these techniques

allow researchers to “rewrite” the nucleotide sequence so that specific mutations can be introduced into genes to better understand their function, or mutant versions of genes can be corrected to restore normal function. Collectively, these techniques are known as [DNA editing](#).

One of the newest and most exciting ways to edit DNA is [CRISPR](#) (clustered regularly interspaced short palindromic repeats), and it was discovered in an unexpected way. Researchers noted that about half of all species of bacteria and most species of Archaea contain similar small segments of DNA of about 20–50 base pairs derived from plasmids or viruses, but their function was, at first, a mystery. Later, it was discovered that they play a role in bacterial defense. When a bacterium is infected by a virus for the first time, it makes a copy of part of the viral genome and incorporates it into its genome. On subsequent infection by the same virus, the DNA copy of the viral genome is transcribed to RNA that combines with a protein that has a DNA-cleaving function. The RNA serves as a guide to identify target DNA in the virus by complementary base pairing, and the protein cleaves the target DNA, thus ending the viral threat. In this way, bacteria “remember” and defend themselves from past infections. The phrase “clustered regularly interspaced short palindromic repeats” describes the organization of the viral DNA segments in the bacterial genome.

In modern genetic engineering, the CRISPR mechanism is put to practical use to alter the nucleotide sequence of almost any gene in any kind of cell. One method is outlined in [Fig. 12.21](#). Once researchers

have identified a gene or DNA sequence they want to edit, they need to introduce, at different points in the process, three types of molecules into a cell containing that target DNA: a guide RNA that has been engineered to be complementary to the target DNA; a gene for a protein called Cas9 that cleaves DNA when it associates with the guide RNA; and a piece of DNA that acts as a template, with the desired new sequence for the target DNA. The target DNA will be identified by the guide RNA, cleaved by Cas9, and then replaced with the sequence of the template DNA.

**FIG. 12.21 DNA editing.** In this example, CRISPR guide RNA and its associated protein are used to cleave target DNA, and double-stranded template DNA is used in DNA repair to alter its sequence.

The first step is to transform a cell with a plasmid that contains sequences that code for a CRISPR guide RNA as well as for Cas9. The guide RNA contains a region that can form a hairpin-shaped structure, as well as a region that researchers previously engineered to have bases

complementary to the target DNA ([Fig. 12.21a](#)). When the guide RNA undergoes base pairing with the target DNA, Cas9 cleaves the target DNA ([Fig. 12.21b](#)). Exonucleases in the cell then expand the gap ([Fig. 12.21c](#)). The gap can be repaired using the newly introduced template DNA for editing the target DNA ([Fig. 12.21d](#)). This editing template DNA contains a sequence of interest to replace the degraded sequence of the target DNA, and is flanked by sequences complementary to the target. The strands of the gapped target DNA undergo base pairing with the complementary ends of the editing template, and DNA synthesis elongates the target DNA strands and closes the gap ([Fig. 12.21d](#)). The result is that the target DNA is restored, but its sequence has been altered according to the sequence present in the editing template ([Fig. 12.21e](#)).

DNA editing by CRISPR is technically straightforward and highly efficient. The method has generated great interest because of its potential to correct genetic disorders of the blood, immune system, or other tissues and organs in which only a subset of cells with restored function can alleviate symptoms. CRISPR technology is so powerful that it can be used to insert new genes or change existing genes in virtually any cell type from any type of organism. In principle, the method could also be used to manipulate human germ cells, thereby affecting future generations. The uses and potential risks of human gene editing prompted a 2015 meeting of experts from around the world to discuss the science, ethics, and governance of the research, which resulted in a statement urging caution in the use of the technology to alter human germ cells.

### Self-Assessment Questions

11. In making recombinant DNA molecules that combine restriction fragments from different organisms, researchers usually prefer restriction enzymes such as *Bam*HI or *Hind*III that generate fragments with “sticky ends” (ends with overhangs) rather than enzymes such as *Hpa*I or *Sma*I that generate fragments with “blunt ends” (ends without overhangs). Can you think of a reason for this preference?
12. How can recombinant DNA techniques be used to express a mammalian gene in bacteria?

## CORE CONCEPTS SUMMARY

**12.1 DNA REPLICATION:** In DNA replication, a single parental molecule of DNA produces two daughter molecules.

DNA replication involves the separation of the two strands of the double helix at a replication fork and the use of these strands as templates to direct the synthesis of new strands. [page 257](#)

DNA replication is semiconservative, meaning that each daughter DNA molecule consists of a newly synthesized strand and a strand that was present in the parental DNA molecule. [page 257](#)

Nucleotides are added to the 3' end of the growing strand. Therefore, synthesis proceeds in a 5'-to-3' direction. [page 258](#)

Because synthesis occurs in a 5'-to-3' direction, at the replication fork, one new strand is synthesized continuously (the leading strand) and the other is synthesized in small pieces that are ligated together (the lagging strand). [page 261](#)

DNA polymerase requires RNA primers for DNA synthesis. [page 261](#)

DNA polymerase can correct its own mistakes by detecting a pairing mismatch between a template base and an incorrect new base. [page 263](#)

**12.2 REPLICATION OF CHROMOSOMES:** The replication of linear chromosomal DNA requires mechanisms that ensure efficient and complete replication.

Linear chromosomal DNA has many origins of replication, and replication proceeds from all of these almost simultaneously. [page 264](#)

Telomerase prevents chromosomes from shortening after each round of replication by adding a short stretch of DNA to the ends of chromosomes. [page 264](#)

**12.3 DNA TECHNIQUES:** Techniques for manipulating DNA follow from the basics of DNA structure and replication.

The polymerase chain reaction (PCR) is a technique for amplifying a segment of DNA. [page 267](#)

PCR requires a DNA template, DNA polymerase, the four nucleoside triphosphates, and two primers. It is a repeated cycle of denaturation, annealing, and extension. [page 267](#)

Gel electrophoresis allows DNA fragments to be separated according to size, with small fragments migrating farther than big fragments in a gel. [page 269](#)

Restriction enzymes cut DNA at specific recognition sequences called restriction sites, which cut DNA and leave a single-stranded overhang or a blunt end. [page 269](#)

In DNA denaturation, the two strands of a single DNA molecule separate from each other. In DNA renaturation or hybridization, two complementary strands come back together again. [page 270](#)

A Southern blot involves using a filter paper as a substrate for DNA fragments that have been cut up by restriction enzymes and

hybridized to a probe. [page 271](#)

In Sanger sequencing of DNA, dideoxynucleotide chain terminators are used to stop the DNA synthesis reaction and produce a series of short DNA fragments from which the DNA sequence can be determined. [page 272](#)

New DNA sequencing technologies are being developed to increase the speed and decrease the cost of sequencing, perhaps making it possible to sequence everyone's personal genomes. [page 273](#)

**12.4 GENETIC ENGINEERING:** Genetic engineering allows researchers to alter DNA sequences in living organisms.

A recombinant DNA molecule can be made by cutting DNA from two organisms with the same restriction enzyme and then using DNA ligase to join them. [page 274](#)

Recombinant DNA is the basis for genetically modified organisms (GMOs), which offer both potential benefits and risks. [page 275](#)

Almost any DNA sequence in an organism can be altered by means of a form of DNA editing called CRISPR, which uses modified forms of molecules found in bacteria and archaeons that can cleave double-stranded DNA at a specific site. [page 276](#)

## CHAPTER 13 Genomes

CSP\_iDesign/AGE Fotostock

### CORE CONCEPTS

**13.1 GENOME SEQUENCING:** A genome is the genetic material of a cell, organism, organelle, or virus, and its sequence is the order of bases along the DNA or (in some viruses) RNA.

**13.2 GENOME ANNOTATION:** Researchers annotate genome sequences to identify genes and other functional elements.

**13.3 GENES, GENOMES, AND ORGANISMAL COMPLEXITY:**

The number of genes in a genome and the size of a genome do not correlate well with the complexity of an organism.

**13.4 ORGANIZATION OF GENOMES:** The orderly packaging of DNA allows it to carry out its functions and fit inside the cell.

**13.5 VIRUSES AND VIRAL GENOMES:** Viruses have diverse genomes, but all require a host cell to replicate.

---

In [Chapter 12](#), we saw how small pieces of DNA are isolated, identified, and sequenced. This technology has advanced to the point where the complete genome sequences for thousands of species have been determined, including those of humans and our closest primate relatives, as well as dozens of other mammals. The term **genome** refers to the genetic material of an organism, cell, nucleus, organelle, or virus. Some genomes, like that of HIV, are small, whereas others, like the human genome, are large. Technically, the human genome refers to the DNA in the chromosomes present in a sperm or egg. However, the term is often used informally to mean all of the genetic material in an organism. So your personal genome consists of the DNA in two sets of chromosomes, one inherited from each parent, plus a much smaller mitochondrial genome inherited from your mother. The human genome sequence is so long that printing it in the size of the type used in this book would require 1.5 million pages. As we will see, however, the human genome is far from the largest among organisms.

The sequence of a genome is a long string of A's, T's, G's, and C's, which represent the order of bases present in successive nucleotides along the DNA molecules in the genome. However, a genome sequence, on its own, is not very useful to scientists. Additional research is required to understand what proteins and other molecules are encoded in the genome sequence, and to learn when these molecules are produced during an organism's lifetime and what they do.

In this chapter, we discuss how the sequence of a genome is determined and analyzed to reveal its key biological features, such as the protein-coding genes. We also examine what other kinds of DNA sequences are present in genomes and how these sequences are organized, with special emphasis on the human genome. Finally, we explore the diversity of genome types present in viruses.

# 13.1 GENOME SEQUENCING

What exactly is a genome? Originally, the term referred to the complete set of chromosomes present in a reproductive cell, like a sperm or an egg, which in the human genome is 23 chromosomes. The word “genome” is almost as old as the word “gene,” and it was coined at a time when chromosomes were thought to consist of densely packed genes lined up one after another. A gene, as you may recall from [Chapter 3](#), is a region of DNA associated with some function in the cell or organism. Almost all genes are initially transcribed into RNA, which may be chemically modified or processed. For some genes, the processed RNA can function on its own, but for most genes the processed RNA codes for protein ([Chapter 4](#)).

Chromosomes consist primarily of DNA and associated proteins, and the genetic information in the chromosomes resides in the DNA. One might therefore define the genome as the DNA molecules that are transmitted from parents to offspring. This definition has the advantage of including the DNA in organisms that lack true chromosomes, such as bacteria and archaeons, as well as eukaryotic organelles that contain their own DNA, such as mitochondria and chloroplasts. However, a definition restricted to DNA is too narrow because it excludes viruses like HIV, whose genetic material consists of RNA. Defining a genome as the genetic material transmitted from parent to offspring therefore embraces all known cellular forms of life, all known organelles, and all viruses.

In this first section, we focus on how genomes are sequenced, building on the DNA sequencing technology introduced in [Chapter 12](#).

# Complete genome sequences are assembled from smaller pieces.

In [Chapter 12](#), we discussed a method of DNA sequencing known as Sanger sequencing. Sequencing methods are now automated to the point where specialized machines can determine the sequence of billions of DNA nucleotides in a single day. However, even with recent advances, the data are obtained in the form of short sequences, typically less than a few hundred nucleotides long. If you are interested in sequencing a short DNA fragment, these technologies work well. However, let's say you are interested in the sequence of human chromosome 1, which includes a DNA molecule approximately 250 million nucleotides long. How can you sequence a DNA molecule as long as that?

In one approach, the single long DNA molecule is first broken into small fragments, each of which is short enough to be sequenced by existing technologies. Even though the sequence data obtained from a small DNA fragment is only a minuscule fraction of the length of the DNA molecules in most genomes, each run of an automated sequencing machine yields hundreds of millions of these short sequences from random locations throughout the genome. To sequence a whole genome, researchers typically sequence such a large number of random DNA fragments that, on average, any particular small region of the genome is sequenced 10–50 times. This redundancy is necessary to minimize both the number of errors present in the final genome sequence and the number and size of gaps where the genome sequence is incomplete.

When the sequences of a sufficient number of short stretches of the genome have been obtained, the next step is **sequence assembly**: The short sequences are put together in the correct order to generate the long, continuous sequence of nucleotides in the DNA molecule present in each chromosome.

Assembly is accomplished using complex computer programs, but the principle is simple. The short sequences are assembled according to their overlaps, as illustrated in **Fig. 13.1**, which uses a sentence to represent the nucleotide sequence. This approach is called **shotgun sequencing** because the sequenced fragments do not originate from a particular gene or region but from sites scattered randomly across the chromosome.

#### HOW DO WE KNOW?

### FIG. 13.1

## How are whole genomes sequenced?

#### BACKGROUND

DNA sequencing technologies can only determine the sequence of DNA fragments far smaller than the genome itself. How can the sequences of these small fragments be used to determine the sequence of an entire genome? In the early years of genome sequencing, many researchers thought that it would be necessary to know first where in the genome each fragment originated before sequencing it. A group at Celera Genomics reasoned that if so many fragments were sequenced that the ends of one would almost always overlap with those of others, then a computer program with sufficient power might be able to assemble the short sequences to reveal the sequence of the entire genome. By January 2000,

Celera Genomics announced that it had assembled 90% of the human genome using its new computational methods.

### HYPOTHESIS

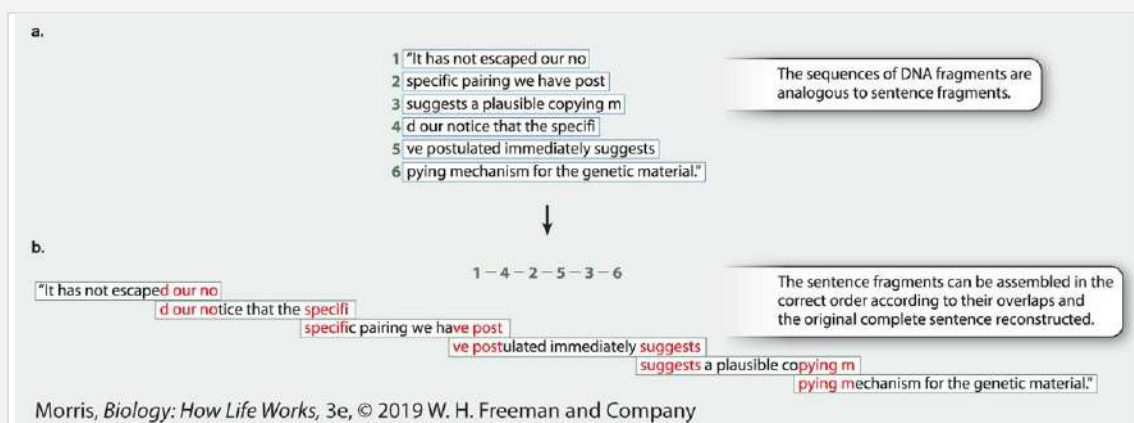

A genome sequence can be determined by sequencing small, randomly generated DNA fragments and assembling them into a complete sequence by matching regions of overlap between the fragments.

### EXPERIMENT

Hundreds of millions of short sequences from the genome of the fruit fly, *Drosophila melanogaster*, were sequenced. [Fig. 13.1a](#) shows examples of overlapping fragments, using a sentence from Watson and Crick's original paper on the chemical structure of DNA as an analogy.

### RESULTS

The computer program the group had written to assemble the fragments worked. The researchers were able to sequence the entire *Drosophila* genome by piecing together the fragments according to their overlaps. In the sentence analogy, the fragments ([Fig. 13.1a](#)) can be assembled into the complete sentence ([Fig. 13.1b](#)) by matching the overlaps between the fragments.

### CONCLUSION

The hypothesis was supported: Celera Genomics was able to determine the entire genomic sequence of an organism by sequencing small, random fragments and piecing them together at their overlapping ends.

#### FOLLOW-UP WORK

Today, computational methods are routinely used to assemble genome sequences. Computer assembly is also used to infer the genome sequences of hundreds of bacterial species simultaneously—for example, in bacterial communities sampled from seawater or from the human gut.

SOURCE Adams, M. D., et al. 2000. “The Genome Sequence of *Drosophila melanogaster*.” *Science* 287:2185–2195.

## Sequences that are repeated complicate sequence assembly.

Sequence assembly is not quite as straightforward as [Fig. 13.1](#) suggests. Real sequences are composed of the nucleotides A, T, G, and C, and any given short sequence could come from either strand of the double-stranded DNA molecule. Therefore, the overlaps between fragments must be long enough both to ensure that the assembly is correct and to determine from which strand of DNA the short sequence originated.

Some features of genomes present additional challenges to sequence assembly, and the limitations of the computer programs for handling such features require hands-on assembly. Chief among these complicating features is the problem of repeated sequences known collectively as [repetitive DNA](#).

There are many types of repeated sequences in eukaryotic genomes, and some are shown in [Fig. 13.2](#). The repeated sequence may be several thousand nucleotides long and present in multiple identical or nearly identical copies. These long repeated sequences may be

dispersed throughout the genome ([Fig. 13.2a](#)), or they may be in tandem, meaning that they are next to each other ([Fig. 13.2b](#)).

The difficulty with long repeated sequences is that they typically are much longer than the short fragments sequenced by automated sequencing. As a result, the repeat may not be detected at all. If the repeat is actually detected, there is no easy way of knowing the number of copies of the repeat, that is, whether the DNA molecule includes two, three, four, or any number of copies of the repeat. Sometimes, researchers can use the ends of repeats, where the fragments overlap with an adjacent, nonrepeating sequence, as a guide to the position and number of repeats.

To illustrate the assembly problems caused by repeated sequences, let's consider an analogy. In Shakespeare's play *Hamlet*, the word "Hamlet" occurs about 500 times throughout the text, similar to a dispersed repeat ([Fig. 13.2a](#)). If you chose short sequences of letters from the play at random and found the sequence "Hamlet" or "amlet" or "Haml," you would have no way of knowing which of the 500 "Hamlets" these letters came from. Only if you found sequences that contained "Hamlet" overlapping with adjacent unique text could you identify their origin.

In another type of repeat, the repeating sequence is short. It could be as short as two nucleotides, such as AT, repeated over and over again in a stretch of DNA ([Fig. 13.2c](#)). Short repeating sequences of this kind are troublesome for sequencing machines because any single-stranded fragment consisting of alternating AT bases can fold back upon itself to form a double-stranded structure in which A is paired with T. Such structures are more stable than the unfolded single-stranded structures and are not easily sequenced. Similarly, the sequence 5'-AAAAAATTTTTT-3' can also fold back itself to form a hairpin because the 5'-AAAAAA-3' is complementary to the 3'-TTTTTT-5'.

### CASE 3 YOUR PERSONAL GENOME: YOU, FROM A TO

T

## Why sequence your personal genome?

The goal of the Human Genome Project, which began in 1990, was to sequence the human genome as well as the genomes of certain

organisms used as models in genetic research. The model organisms chosen are the mainstays of laboratory biology—a species each of bacteria, yeast, nematode worm, fruit fly, and mouse. By 2003, the genome sequences of these model organisms had been completed, as well as that of the human genome. By then, the cost of sequencing had become so low and the sequence output so high that many more genomes were sequenced than originally planned. Genome sequencing is even cheaper today, and soon you will be able to choose to have your personal genome sequenced.

Why sequence more genomes? And if the human genome is sequenced, why sequence yours? As we saw in [Case 3 Your Personal Genome](#), there is really no such thing as *the* human genome, any more than there is *the* fruit fly genome or *the* mouse genome. With the exception of identical twins, every person's genome is unique, the product of a fusion of a unique egg with a unique sperm. The sequence that is called “the human genome” is actually a composite of sequences from different individuals. This sequence is nevertheless useful because most of us share the same genes and regulatory regions, organized the same way on chromosomes. Detailed knowledge of your own personal genome can be valuable. Our individual DNA sequences differ at millions of nucleotide sites from one person to the next. Some of these differences account in part for the physical differences we see among us; others have the potential to predict susceptibility to disease and response to medication. For Claudia Gilmore, knowledge of the sequence of her *BRCA1* gene had a significant impact on her life.

Determining these differences is a step toward [personalized](#)

medicine, in which an individual's genome sequence, by revealing his or her disease susceptibilities and drug sensitivities, allows treatments to be tailored to that individual. There may come a time, perhaps within your lifetime, when personal genome sequencing becomes part of routine medical testing. Information about a patient's genome will bring benefits, but it will also raise ethical concerns and pose risks to confidentiality and insurability.

#### Self-Assessment Questions

1. DNA sequencing technology has been around since the late 1970s. Why did sequencing whole genomes present a challenge?
2. What is the shotgun method for determining the complete genome sequence of an organism?
3. Repeated sequences can be classified according to their organization in the genome as well as according to their function. What are two examples of each?
4. Let's say that a stretch of repeated AT is successfully sequenced. From what you know of the difficulties of sequencing long repeated sequences, what other problems might you encounter in assembling these fragments?

## 13.2 GENOME ANNOTATION

A goal of biology is to identify all the macromolecules in biological systems and understand their functions and the ways in which they interact. This research has practical applications: increased understanding of the molecular and cellular basis of disease, for example, can lead to improved diagnosis and treatment.

The value of genome sequencing in identifying macromolecules is that the genome sequence contains, in coded form, the nucleotide sequence of all RNA molecules transcribed from the DNA as well as the amino acid sequence of all proteins. There is a catch, however. A genome sequence is merely an extremely long list of A's, T's, G's, and C's that represent the order in which nucleotides occur along the DNA in one strand of the double helix. (Because of complementarity, knowing the sequence of one strand specifies the other.) The catch is that in multicellular organisms, not all the DNA is transcribed into RNA, and not all the RNA that is transcribed is translated into protein. Therefore, genome sequencing is just the first step in understanding the function of any particular DNA sequence. Following genome sequencing, the next step is to identify the locations and functions of the various types of sequence present in the genome.

### Genome annotation identifies various types of sequence.

Genomes contain many different types of sequence, among them protein-coding genes ([Chapters 3](#) and [4](#)). Protein-coding genes are themselves composed of different regions, including transcribed and

untranscribed regions. Transcribed regions contain exons with codons that specify the amino acid sequence of a polypeptide chain and introns that are removed during RNA processing. Untranscribed regions include promoters indicating where RNA transcription begins and other elements that specify when and where the RNA transcript is produced. Genomes also contain coding sequences for RNAs that are not translated into protein (noncoding RNAs), such as ribosomal RNA, transfer RNA, and other types of small RNA molecule. Although much of the DNA in the genomes of multicellular organisms is transcribed at least in some cell types, the functions of a large portion of these transcripts in metabolism, physiology, development, or behavior are unknown.

**Genome annotation** is the process by which researchers identify the various types of sequence present in genomes. Genome annotation is essentially an exercise in adding commentary to a genome sequence that identifies which types of sequence are present and where they are located. It can be thought of as a form of pattern recognition, where the patterns are regularities in a sequence that are characteristic of protein-coding genes or other types of sequence.

An example of genome annotation is shown in **Fig. 13.3**. Genes present in one copy per genome are indicated in orange. Most single-copy genes are protein-coding genes. In some computer programs that analyze genomes, the annotation of a single-copy gene also specifies any nearby regulatory elements that control transcription, the intron–exon boundaries in the gene, and any known or predicted alternative forms in which the introns and exons are spliced (**Chapter 3**). Each

single-copy gene is given a unique name and its protein product is identified. Note in [Fig. 13.3](#) that single-copy genes can differ in size from one gene to the next. The annotations in [Fig. 13.3](#) also specify the locations of sequences that encode RNAs that are not translated into proteins, as well as various types of repeated sequence. Most genomes also contain some genes that are present in multiple copies that originate from gene duplication. However, these are usually identifiable in the same way as single-copy genes because the copies often differ enough in sequence that they can be distinguished.

Small genomes, such as that of HIV and other viruses, can be annotated by hand, but for large genomes like the human genome, computers are essential. In the human genome, some protein-coding genes extend for more than a million nucleotides. Roughly speaking, if

the sequence of the approximately 3 billion nucleotides in a human egg or sperm was printed in normal-sized type like this, the length of the ribbon would stretch 4000 miles (6440 kilometers), which is about the distance from Fairbanks, Alaska, to Miami, Florida. By contrast, for the approximately 10,000 nucleotides in the HIV genome, the ribbon would extend a mere 70 feet (21 meters).

Genome annotation is an ongoing process because, as macromolecules and their functions and interactions become better understood, the annotations to the genome must be updated. A sequence that is annotated as nonfunctional today may be found to have a function tomorrow. For this reason, the annotation of certain genomes—including the human genome—will certainly continue to change.

## Genome annotation includes searching for sequence motifs.

Because genome annotation is essentially pattern recognition, researchers begin annotating a genome by identifying patterns called **sequence motifs**, which are telltale sequences of nucleotides that indicate what types of function (or absence of function) may be encoded in a particular region of the genome (**Fig. 13.4**). Researchers can find sequence motifs in the DNA itself or in the RNA sequence inferred from the DNA sequence. Once identified, sequence motifs are typically confirmed by experimental methods. One sequence motif we have already encountered in **Chapter 3** is a promoter, a DNA sequence where RNA polymerase and associated proteins bind to the DNA to initiate transcription.

FIG. 13.4 Some common sequence motifs useful in genome annotation. (a) An open reading frame; (b) a noncoding RNA molecule; (c) transcription factor binding sites.

Another example of a sequence motif is an **open reading frame (ORF)**, which researchers can identify in the DNA sequence or in the RNA sequence inferred from the DNA sequence ([Fig. 13.4a](#)). An ORF is a long string of nucleotides that, if transcribed and processed into

messenger RNA, results in a set of codons for amino acids that does not contain a stop codon. The presence of an ORF motif alone is enough for a researcher to annotate the DNA segment as potentially protein coding. The qualifier “potentially” is necessary because ORFs identified in a DNA or RNA sequence may not actually produce a protein. For this reason, they are often called putative ORFs. A region containing a putative ORF may exist merely by chance; a putative ORF may not be transcribed; or a putative ORF might be transcribed but not translated if it produces a noncoding RNA or is found in what turns out to be in an intron. In the next section, we discuss how the analysis of messenger RNA sequences can determine whether a putative ORF is an actual ORF in DNA coding for protein.

[Fig. 13.4b](#) shows another sequence motif present in a hypothetical RNA transcript inferred from the DNA sequence. The nucleotide sequence at one end of the RNA is complementary to that at the other end, so the single-stranded molecule is able to fold back on itself and undergo base pairing to form a hairpin-shaped structure. Such hairpin structures are characteristic of certain types of RNA that function in gene regulation ([Chapter 18](#)). The DNA from which this RNA is transcribed also has complementary sequences on either end.

[Fig. 13.4c](#) shows one more type of sequence motif—a short sequence that is a binding site for DNA-binding proteins called transcription factors, which initiate transcription ([Chapter 3](#)). Transcription factor binding sites are often present in multiple copies (two copies, in red in [Fig. 3.14c](#)) and in either strand of the DNA. Sometimes they are located near the region of a gene where

transcription is initiated because the transcription factor helps determine when the gene will be transcribed. However, they can also be located far upstream of the gene, downstream of the gene, or in introns, so their identification is difficult.

## Comparison of genomic DNA with messenger RNA reveals the intron–exon structure of genes.

In annotating an entire genome, researchers typically make use of information outside the genome sequence itself. This information may include sequences of messenger RNA molecules that are isolated from various tissues or various stages of development of the organism.

Recall from [Chapter 3](#) that messenger RNA (mRNA) molecules have undergone processing and are therefore usually simpler than the DNA sequences from which they are transcribed. For example, introns are removed and exons are spliced together. The resulting mature mRNA therefore contains a long sequence of codons uninterrupted by a stop codon—in other words, an ORF. The ORF in an mRNA is the region that is actually translated into protein.

One aspect of genome annotation is the determination of which portions of the genome sequence correspond to sequences in mRNA transcripts. An example is shown in [Fig. 13.5](#), which compares the DNA and mRNA for the beta ( $\beta$ ) chain of hemoglobin, the oxygen-carrying protein in red blood cells. Note that the genomic DNA contains some sequences present in the mRNA, which correspond to exons, and some sequences that are not present in the mRNA, which

correspond to introns. Comparison of mRNA with genomic DNA therefore reveals the intron–exon structure of protein-coding genes. In fact, introns were first discovered by comparing  $\beta$ -globin mRNA with genomic DNA.

FIG. 13.5 Identification of exons and introns by comparison of genomic DNA with mRNA sequence.

**An annotated genome summarizes knowledge, guides research, and reveals evolutionary relationships among organisms.**

Genome annotation, which aims to identify all the functional and repeat sequences present in the genome, is an imperfect science. Even in a well-annotated genome, some protein-coding sequences or other important features may be overlooked, and occasionally the annotation of a sequence motif is incorrect.

Because researchers often have to rely on sequence motifs alone and not experimental data, their descriptions may be vague. For example, a

common annotation in large genomes is “hypothetical protein.” In some cases, such as the genome of the malaria parasite, this type of annotation accounts for about 50% of the possible protein-coding genes. There is no hint of what a hypothetical protein may do or even whether it is actually produced because it is determined solely by the presence of a putative ORF in the genomic sequence and not by the presence of actual mRNA or protein. Other annotations might be “DNA-binding protein,” “possible hairpin RNA,” or “tyrosine kinase”—with no additional detail about these motifs’ functions or relationships to other sequences. In short, although some genome annotations summarize experimentally verified facts, many others are hypotheses and guides to future research.

Genome sequences contain information about ancestry and evolution, and so comparisons among genomes can reveal how different species are related. For example, the sequence of the human genome is significantly more similar to that of the chimpanzee than to that of the gorilla, indicating a more recent common ancestry of humans and chimpanzees ([Chapter 23](#)).

Analysis of the similarities and differences in protein-coding genes and other types of sequence in the genomes of different species is an area of study called [comparative genomics](#). Such studies help us understand how genes and genomes evolve. They can also guide genome annotation because the sequences of important functional elements are often very similar among genomes of different organisms. Sequences that are similar in different organisms are said to be [conserved](#). If a conserved sequence is found in several different

organisms, researchers might look for that sequence in the genome they are annotating. A sequence motif that is conserved is likely to be important, even if its function is unknown, because it has changed very little over evolutionary time.

## The HIV genome illustrates the utility of genome annotation and comparison.

HIV and related viruses provide an example of how genomes are annotated and how comparisons among genome sequences can reveal evolutionary relationships. A [virus](#) is a small infectious agent that contains a nucleic acid genome packaged inside a protein coat called a [capsid](#). Viruses can bind to receptor proteins on cells of the host organism, enabling the viral genome to enter the cell. Infection of a host cell is essential to viral reproduction because viruses use cellular ATP and hijack cellular machinery to replicate, transcribe, and translate their genome in order to make more viruses. Later in this chapter, we will see that viruses can differ in the types of nucleic acid that make up their genome and how their messenger RNA is produced, but here we consider only the genome of HIV.

Whereas the genome of all cells consists of double-stranded DNA, the genome of HIV is single-stranded RNA. The sequence of the HIV genome identifies it as a retrovirus that replicates by a DNA intermediate that can be incorporated into the host genome. More narrowly, the sequence of the HIV genome groups it among the mammalian lentiviruses, so named because of the long lag between the initial time of infection and the appearance of symptoms (*lenti* means “slow”).

**Fig. 13.6** shows the evolutionary relationships among a sample of lentiviruses, which are grouped according to the similarity of their genome sequences. The evolutionary tree shows that closely related viruses have closely related hosts. For example, simian lentiviruses are more closely related to one another than they are to cat lentiviruses. This observation implies that the genomes of the viruses evolve along with the genomes of their hosts. A second feature shown by the evolutionary tree is that human HIV originated from at least two separate simian viruses that switched hosts from simians (most likely chimpanzees) to humans.

FIG. 13.6 Evolutionary relationships among viruses related to HIV. *Data from A. Katzourakis, M. Tristem, O. G. Pybus, and R. J. Gifford, 2007, "Discovery and Analysis of the First Endogenous Lentivirus," Proceedings of the National Academy of Sciences USA 104(15): 6261–6265.*

The annotated sequence of the HIV genome tells us a lot about the biology of this virus (**Fig. 13.7**). Many details are left out here, but the

main point is to show the functional elements of HIV in the form of an annotated genome. The open reading frame denoted *gag* encodes protein components of the capsid, *pol* encodes proteins needed for reverse transcription of the viral RNA into DNA and incorporation into the host genome, and *env* encodes proteins that are embedded in the lipid envelope. The annotation in [Fig. 13.7](#) also includes the genes *tat* and *rev*, which are encoding proteins that are essential for the HIV life cycle, as well as the genes *vif*, *vpr*, *vpu*, and *nef*, which encode proteins that enhance virulence in organisms. Identification of the genes necessary to complete the HIV cycle is the first step to finding drugs that can interfere with the cycle and prevent infection.

FIG. 13.7 The annotated genome of HIV.

### Self-Assessment Questions

5. What is the purpose of genome annotation?
6. What does a comparison of the sequence of genomic DNA to messenger RNA indicate about the structure of a gene?
7. How can comparing the sequences of two genomes help to infer evolutionary relationships?

## 13.3 GENES, GENOMES, AND ORGANISMAL COMPLEXITY

Before whole-genome sequencing, molecular biology and evolution research tended to focus on single genes. Researchers studied how individual genes are turned on and off, and how a gene in one organism is related to a gene in another organism. Now, with the availability of genome sequences from multiple species, it is possible to make comparisons across full genomes. Some of the results have been striking.

### Gene number is not a good predictor of biological complexity.

The complete genome sequences of many organisms allow us to make comparisons among them ([Table 13.1](#)). As different genomes were sequenced and annotated, it came as something of a surprise to find that humans have about the same number of protein-coding genes as many organisms with much smaller genomes. For example, the small flowering plant *Arabidopsis thaliana* has a genome only about 5% as large as that of humans, but the plant has at least as many protein-coding genes. The nematode worm *Caenorhabditis elegans* contains only 959 cells, of which 302 are nerve cells that form the worm's brain. Humans have 100 trillion cells, of which 100 billion are nerve cells. Despite having 100 million times as many cells as the worm, we have roughly the same number of protein-coding genes. Another example of the disconnect between level of complexity and genome size is the observation that the genome size of the mountain

grasshopper *Podisma pedestris* is more than 100 times that of the fruit fly *Drosophila melanogaster*. Although there is no agreed-upon definition of organismal complexity, it would be hard to make a case that grasshoppers are any more or less complex than fruit flies.

### TABLE 13.1 Gene Numbers of Several Organisms.

Humans have more genes than fruit flies and nematode worms, but not as many as might be expected on the basis of complexity.

| COMMON NAME   | SPECIES NAME                    | APPROXIMATE NUMBER OF PROTEIN-CODING GENES |
|---------------|---------------------------------|--------------------------------------------|
| Mustard plant | <i>Arabidopsis thaliana</i>     | 27,000                                     |
| Human         | <i>Homo sapiens</i>             | 25,000                                     |
| Nematode worm | <i>Caenorhabditis elegans</i>   | 22,000                                     |
| Fruit fly     | <i>Drosophila melanogaster</i>  | 17,000                                     |
| Baker's yeast | <i>Saccharomyces cerevisiae</i> | 6000                                       |
| Gut bacterium | <i>Escherichia coli</i>         | 4000                                       |

Data from “Sequence Composition of the Human Genome” in International Genome Sequencing Consortium, 2001, “Initial Sequencing and Analysis of the Human Genome” (PDF). *Nature* 409(6822): 860–921, doi:10.1038/35057062, PMID 11237011.

On the other hand, some organisms are able to do more things with the genes they have than other organisms. For example, the expression of protein-coding genes can be regulated in many subtle ways, causing different gene products to be made in different amounts in different cells at different times ([Chapters 18](#) and [19](#)). Differential gene expression allows the same protein-coding genes to be deployed in

different combinations to yield a variety of distinct cell types. In addition, proteins can interact with one another so that, even though there are relatively few types of protein, they are capable of combining in many different ways to perform different functions. We also have seen that a single gene may yield multiple proteins, either because of alternative splicing (different exons are spliced together to make different proteins) or posttranslational modification (proteins undergo biochemical changes after they have been translated).

Overall, the data in [Table 13.1](#) pose many tantalizing evolutionary questions and suggest that major evolutionary changes can be accomplished not only by the acquisition of whole new genes, but also by modifying existing genes and their regulation in subtle ways.

## Viruses, bacteria, and archaeons have small, compact genomes.

Not only can we compare numbers of genes, we can also compare sizes of genomes in different organisms. Before making such comparisons, we need to understand how genome size is measured. Genomes are measured in numbers of base pairs, and the yardsticks of genome size are a thousand base pairs (a kilobase, kb), a million base pairs (a megabase, Mb), and a billion base pairs (a gigabase, Gb).

Most viral genomes range in size from 3 kb to 300 kb, but a few are very large. Giant viruses, which infect certain species of amoebae, have genomes of approximately 1.5 Mb. These genomes contain approximately 1500 genes, including genes for nearly every component needed for translation except for ribosomes, as well as

genes for sugar, lipid, and amino acid metabolism that are not found in other viruses.

The largest viral genome is three times as large and contains three times as many genes as the genome of the bacterium *Mycoplasma genitalium*. At 580 kb and encoding only 471 genes, the genome of *M. genitalium* is the smallest known among free-living bacteria—those capable of living entirely on their own. The complete sequence of small bacterial genomes has allowed researchers to define the smallest, or minimal, genome (and, therefore, the minimal set of proteins) necessary to sustain life. Current findings suggest that the minimum number of genes necessary to encode all the functions essential to life is approximately 500.

The genomes of bacteria and archaeons are information dense, meaning that most of the genome has a defined function. Roughly speaking, 90% or more of their genomes consist of protein-coding genes (although, in many cases, the protein has an unknown function). Bacterial genomes range in size from 0.5 to 10 Mb. The bigger genomes have more genes, allowing these bacteria to synthesize small molecules that other bacteria have to scrounge for, or to use chemical energy in the covalent bonds of substances that other bacteria cannot. Archaeons, whose genomes range in size from 0.5 to 5.7 Mb, have similar capabilities.

**Among eukaryotes, no relationship exists between genome size and**

## organismal complexity.

In eukaryotes, just as the number of genes does not correlate well with organismal complexity, the size of the genome is unrelated to the metabolic, developmental, and behavioral complexity of the organism ([Table 13.2](#)). The range of genome sizes is huge, even among similar organisms ([Fig. 13.8](#)). For comparison, [Fig. 13.8](#) also shows the range of genome sizes among bacteria and archaeons. The largest eukaryotic genome exceeds the size of the smallest by a factor of more than 500,000—and both the smallest and the largest are found among protozoa. The range among flowering plants (angiosperms) is about three orders of magnitude, and the range among animals is about seven orders of magnitude. One species of lungfish has a genome size more than 45 times larger than the human genome ([Table 13.2](#)). Clearly, no relationship exists between the size of the genome and the complexity of the organism.

**TABLE 13.2 Genome Sizes of Several Organisms.** Genome size varies tremendously among eukaryotic organisms, and there is no correlation between genome size and the complexity of an organism.

| COMMON NAME     | SPECIES NAME                   | APPROXIMATE GENOME SIZE (Mb) |
|-----------------|--------------------------------|------------------------------|
| Fruit fly       | <i>Drosophila melanogaster</i> | 180                          |
| Fugu fish       | <i>Fugu rubripes</i>           | 400                          |
| Boa constrictor | <i>Boa constrictor</i>         | 2100                         |
| Human           | <i>Homo sapiens</i>            | 3100                         |
| Locust          | <i>Schistocerca gregaria</i>   | 9300                         |
| Onion           | <i>Allium cepa</i>             | 18,000                       |

|          |                                |         |
|----------|--------------------------------|---------|
| Newt     | <i>Amphiuma means</i>          | 84,000  |
| Lungfish | <i>Protopterus aethiopicus</i> | 140,000 |
| Fern     | <i>Ophioglossum petiolatum</i> | 160,000 |
| Amoeba   | <i>Amoeba dubia</i>            | 670,000 |

Data from “Sequence Composition of the Human Genome” in International Human Genome Sequencing Consortium, 2001, “Initial Sequencing and Analysis of the Human Genome” (PDF). *Nature* 409(6822): 860–921, doi:10.1038/35057062, PMID 11237011.

FIG. 13.8 Ranges of genome size. Even within a single group, genome sizes of different species can vary by several factors of 10. After Fig. 1, p. 186 in T. R. Gregory, 2004, “Macroevolution, Hierarchy Theory, and the C-Value Enigma,” *Paleobiology* 30:179–202.

The disconnect between genome size and organismal complexity is called the **C-value paradox**. The C-value is the amount of DNA in a reproductive cell, and the paradox is the apparent contradiction between genome size and organismal complexity, leading to the difficulty of predicting one based on the other.

Why are some eukaryotic genomes so large? One reason is **polyploidy**, or having more than two sets of chromosomes in the genome. Polyploidy is especially prominent in many groups of plants. Humans have two sets of 23 chromosomes, giving us 46 chromosomes in total. The polyploid bread wheat *Triticum aestivum*, for example, has six sets of seven chromosomes.

Polyploidy has played an important role in plant evolution. Many agricultural crops are polyploid, including wheat, potatoes, olives, bananas, sugarcane, and coffee. Among flowering plants, it is estimated that 30% to 80% of existing species have polyploidy in their evolutionary histories, either because of the duplication of the complete set of chromosomes in a single species, or because of hybridization, or crossing, between related species followed by duplication of the chromosome sets in the hybrid (**Fig. 13.9**). Some ferns take polyploidy to an extreme: one species has 84 copies of a set of 15 chromosomes, or 1260 chromosomes altogether.

*Photo source: McPHOTO/age fotostock.*

FIG. 13.9 Polyploidy in plants. A type of crocus known as Golden Yellow was formed by hybridization between two different species, and it contains a full set of chromosomes from each parent. The parental chromosomes in the hybrid are indicated in orange and blue in the diagram on the right.

However, the principal reason for large genomes among some eukaryotes is that their genomes contain large amounts of DNA that do not code for proteins, such as introns and DNA sequences that are present in many copies. These repeated sequences are discussed next.

## About half of the human genome consists of transposable elements and other types of repetitive DNA.

Complete genome sequencing has allowed the different types of noncoding DNA to be specified more precisely in a variety of organisms. It came as a great surprise to learn that in the human genome, only about 2.5% of the genome actually codes for proteins. The other 97.5% includes sequences we have encountered earlier, including introns, noncoding DNA, and other types of repetitive sequences.

In [Fig. 13.10](#), we see the composition of the human genome, including the principal types of repeated sequences. Earlier, we saw how repeated sequences could be classified as dispersed or tandem according to their organization in the genome. In [Fig. 13.10](#), the repeated sequences are classified according to their function. Among the repeated sequences is alpha ( $\alpha$ ) satellite DNA, which consists of tandem copies of a 171-bp sequence repeated near each centromere an average of 18,000 times. The  $\alpha$  satellite DNA is essential for attachment of spindle fibers to the centromeres during cell division ([Chapter 11](#)).

FIG. 13.10 Sequence composition of the human genome.

[Fig. 13.10](#) also shows the proportions of several types of repeated sequence collectively known as [transposable elements](#) (abbreviated

*TE*; also called [transposons](#)), which are DNA sequences that can replicate and insert themselves into new positions in the genome. As a result, they have the potential to increase their copy number in the genome over time. Transposable elements are sometimes referred to as “selfish” DNA because it seems that their only function is to duplicate themselves and proliferate in the genome, making them the ultimate parasite.

Transposable elements make up about 45% of the DNA in the human genome. They can be grouped into two major classes based on the way they replicate. One class consists of [DNA transposons](#), which replicate and transpose by DNA replication and repair. The other class consists of elements that transpose by means of an RNA intermediate. These are called [retrotransposons](#) because their RNA is used as a template to synthesize complementary strands of DNA, a process that reverses the usual flow of genetic information from DNA into RNA (*retro* means “backward”). More than 40% of the human genome consists of various types of retrotransposons, whereas only about 3% of human DNA consists of DNA transposons.

Over the course of evolutionary time, the amount of repetitive DNA in a genome can change drastically, in large part because of the accumulation of transposable elements ([Fig. 13.10](#)). In some genomes, repetitive DNA is maintained over long periods of time even as new species evolve and diversify, whereas in other genomes the amount of repetitive DNA is held in check because of deletion and other processes. The result is that the genomes of different species can contain vastly differing amounts of repetitive DNA, and this accounts

in large part for the C-value paradox.

#### Self-Assessment Questions

8. Given our knowledge of genome sizes in different organisms, would you predict that *Homo sapiens* or the two-toed salamander (*Amphiuma means*) has the larger genome?
9. What are some reasons why, in multicellular eukaryotes, genome size is not necessarily related to the number of protein-coding genes or organismal complexity?

## 13.4 ORGANIZATION OF GENOMES

Regardless of whether an organism has a large or a small genome, the genomes of all organisms are large relative to the size of the cell. For example, if the circular genome of the intestinal bacterium *Escherichia coli* were fully extended, its length would be 200 times greater than the diameter of the cell itself. The fully extended length of DNA in human chromosome 1, our longest chromosome, would be 10,000 times greater than the diameter of the average human cell. Consequently, an enormous length of DNA must be packaged into a form that will fit inside the cell while still allowing the DNA to replicate and carry out its coding functions. The mechanism of packaging differs substantially in bacteria, archaeons, and eukaryotes. We focus here on bacteria and eukaryotes, primarily because less is known about how DNA is packaged in archaeons.

### Bacterial cells package their DNA as a nucleoid composed of many loops.

Bacterial genomes are circular, and the DNA double helix is underwound, which means that it makes fewer turns in going around the circle than would allow every base in one strand to pair with its partner base in the other strand. Underwinding is caused by an enzyme, [topoisomerase II](#), which breaks the double helix, rotates the ends to unwind the helix, and then seals the break. Underwinding creates strain on the DNA molecule, which is relieved by the formation of [supercoils](#), in which the DNA molecule coils on itself. Supercoiling

allows all the base pairs to form, even though the molecule is underwound. You can make your own supercoil by stretching and twirling the ends of a rubber band, and then relaxing the stress slightly to allow the twisted part to form coils around itself ([Fig. 13.11](#)). Supercoils that result from underwinding are called negative supercoils, and those that result from overwinding are positive supercoils. In most organisms, DNA is negatively supercoiled.

In bacteria, the supercoils of DNA form a structure with multiple loops called a **nucleoid** ([Fig. 13.12](#)). The supercoil loops are bound together by proteins. In *E. coli*, the nucleoid has about 100 loops, each containing about 50 kb of DNA. The protein binding that forms the loops as well as the negative supercoiling of the DNA compress the molecule into a compact volume.

 Source: Dr. Klaus Boller/Science Source.

FIG. 13.12 Bacterial nucleoid. The circular bacterial chromosome twists on itself to form supercoils, which are anchored by proteins.

Eukaryotic cells package their DNA as one molecule per chromosome.

Eukaryotic cells also have topoisomerase II enzymes and their DNA is usually negatively supercoiled, but the DNA in chromosomes is packaged very differently from the way it is organized in prokaryotes. Eukaryotic DNA is linear and each DNA molecule forms a single chromosome. In a chromosome, DNA is packaged with proteins to form a DNA-protein complex called **chromatin**.

There are several levels of chromatin packaging (**Fig. 13.13**). First, eukaryotic DNA winds around histone proteins. Histone proteins are found in all eukaryotes, and they interact with any double-stranded DNA, no matter what its sequence is. Histone proteins are evolutionarily conserved, which means that they are very similar in sequence from one organism to the next, and histone proteins from one eukaryote can associate with DNA from another. The histone proteins form the core of a **nucleosome**, which is made up of eight histone proteins: two each of histones H2A, H2B, H3, and H4. Each nucleosome also includes a stretch of DNA wrapped twice around the histone core. The histone proteins are rich in the positively charged amino acids lysine and arginine, which are attracted to the negatively charged phosphate groups in each DNA strand.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 13.13 Levels of chromosome condensation. DNA is wrapped around nucleosomes to form a 10-nm fiber, which can become coiled into a 30-nm fiber and higher-order structures.

This first level of packaging of the DNA is sometimes referred to as “beads on a string,” where the nucleosomes are the beads and the DNA is the string. It is also called a **10-nm fiber** in reference to its diameter,

which is about five times the diameter of the DNA double helix ([Fig. 13.13](#)). In general, these are areas of the genome that are transcriptionally active.

The next level of packaging occurs when the chromatin is more tightly coiled, forming a **30-nm fiber** ([Fig. 13.13](#)). As the chromosomes in the nucleus condense in preparation for cell division, each chromosome becomes progressively shorter and thicker as the 30-nm fiber coils onto itself to form a 300-nm coil, a 700-nm coiled coil, and finally a 1400-nm condensed chromosome in a manner that is still not fully understood. The progressive packaging constitutes **chromosome condensation**, an active, energy-consuming process requiring the participation of several types of proteins.

Greater detail of the structure of a fully condensed chromosome is revealed when the histones are chemically removed ([Fig. 13.14](#)). Without histones, the DNA spreads out in loops around a supporting protein structure called the chromosome **scaffold**. Each loop of relaxed DNA is 30 to 90 kb long and anchored to the scaffold at its base. Before removal of the histones, the loops are compact and supercoiled. Each human chromosome contains 2000–8000 such loops, depending on its size.

Despite intriguing similarities between the nucleoid model in [Fig. 13.12](#) and the chromosome scaffold model in [Fig. 13.14](#), the structures evolved independently and make use of different types of protein to bind the DNA and form the folded structure of DNA and protein. Furthermore, the size of the eukaryotic chromosome is vastly greater than the size of the bacterial nucleoid. To appreciate the difference in scale, keep in mind that the volume of a fully condensed human *chromosome* is five times larger than the volume of a bacterial *cell*.

## The human genome consists of 22 pairs of chromosomes and two sex chromosomes.

As discussed in [Chapter 11](#), the orderly process of meiosis is possible

because chromosomes come in pairs. The pairs usually match in size, general appearance, and position of the centromere, but there are exceptions, such as the *X* and *Y* sex chromosomes. The pairs of chromosomes that match in size and appearance are called **homologous chromosomes**. The members of each pair of homologous chromosomes have the same genes arranged in the same order along their length. If the DNA duplexes in each pair of homologs were denatured, each DNA strand could form a duplex with its complementary strand from the other homolog. There would be some differences in DNA sequence due to genetic variation, but not so many differences as to prevent DNA hybridization.

Chromosome painting illustrates the nearly identical nature of the DNA molecules in each pair of homologs. In this technique, individual chromosomes are isolated from cells in metaphase of mitosis. Metaphase of mitosis is the easiest stage in which to isolate chromosomes because of the availability of chemicals that prevent the spindle from forming. These chemicals block the cell cycle at metaphase, so cells progress to metaphase and then stop.

Once the chromosomes have been isolated, the DNA from each chromosome is fragmented, denatured, and labeled with a unique combination of fluorescent dyes. Under fluorescent light, the dyes give the DNA in each type of chromosome a different color. The fluorescently labeled DNA fragments are then mixed with and hybridized to intact metaphase chromosomes from another cell. Each labeled fragment hybridizes to its complementary sequence in the metaphase chromosomes, “painting” each metaphase chromosome

with dye-labeled DNA fragments.

A chromosome paint of the chromosomes in a human male is shown in [Fig. 13.15](#). [Fig. 13.15a](#) shows the chromosomes in the random orientation in which they were found in the metaphase cell, and [Fig. 13.15b](#) shows them arranged in a standard form called a **karyotype** ([Chapter 11](#)). To make a karyotype, the images of the homologous chromosomes are arranged in pairs from longest to shortest, with the sex chromosomes placed at the lower right. In this case, the sex chromosomes are XY (one X chromosome and one Y chromosome), indicating that the individual is male; in a female, the sex chromosomes are XX (a pair of X chromosomes). Including the sex chromosomes, humans have 23 pairs of chromosomes.

FIG. 13.15 A chromosome paint of chromosomes from a human male. (a)

Condensed chromosomes are “painted” with fluorescent dyes. (b) Chromosomes are arranged in the standard form of a karyotype.

An important observation from the chromosome paint shown in [Fig. 13.15](#) is that the two members of each pair of homologous chromosomes show the same pattern of fluorescent color. This means that a particular labeled DNA fragment hybridized only with the two homologs of one chromosome. Thus, the DNA in each pair of homologous chromosomes is different from that in any other pair of homologous chromosomes.

Higher resolution of human chromosomes can be obtained by the use of stains that bind preferentially to certain chromosomal regions and produce a visible pattern of bands, or crosswise striations, in the chromosomes. One such stain is the Giemsa stain; a Giemsa-stained karyotype is shown in [Fig. 13.16](#). Note that each chromosome has a unique pattern of bands and that homologous chromosomes can readily be identified by their identical banding patterns. Procedures using the Giemsa stain yield about 300 bands that are used as landmarks for describing the location of genes along the chromosome. Such landmarks are also important in identifying specific chromosomal abnormalities associated with diseases, including some childhood leukemias.

FIG. 13.16 Giemsa bands in a karyotype of a human male. Each dashed line marks the position of the centromere.

Every species of eukaryote has its characteristic number of chromosomes. The number differs from one species to the next, with little relation between chromosome number and genome size. Despite variation in number, the rule that chromosomes come in pairs holds up pretty well, with the exception of the sex chromosomes. Polyploids, too, are an exception, but even in naturally occurring polyploids the number of copies of each homologous chromosome is usually an even number, so there are pairs of homologs after all.

The occurrence of chromosomes in pairs allows eukaryotes to reproduce sexually. When reproductive cells are formed during meiotic cell division, each cell receives one and only one copy of each of the pairs of homologous chromosomes ([Chapter 11](#)). When reproductive cells from two individuals fuse to form an offspring cell, the chromosome number characteristic of the species is reconstituted.

# Organelle DNA forms nucleoids that differ from those in bacteria.

Most eukaryotic cells contain mitochondria, and many contain chloroplasts. Each type of organelle has its own DNA, meaning that eukaryotic cells have multiple genomes. Each eukaryotic cell has a [nuclear genome](#) consisting of the DNA in the chromosomes. Cells with mitochondria also have a [mitochondrial genome](#), and those with chloroplasts also have a [chloroplast genome](#).

Because the genome organization and mechanisms of protein synthesis in these organelles resemble those of bacteria, most biologists subscribe to the theory that the organelles originated as free-living bacterial cells that were engulfed by primitive eukaryotic cells billions of years ago ([Chapter 25](#)). In [Chapters 7](#) and [8](#), we saw that the likely ancestor of mitochondria resembled a group of today's non-photosynthetic bacteria (a group that includes *E. coli*), and the likely ancestor of chloroplasts resembled today's photosynthetic cyanobacteria. In both cases, the DNA of the organelles became smaller during the course of evolution because most of the genes were transferred to the DNA in the nucleus. If the products of these transferred genes are needed in the organelles, they are synthesized in the cytoplasm and targeted for entry into the organelles by signal sequences ([Chapter 5](#)).

DNA in mitochondria and chloroplasts is usually circular and exists in multiple copies per organelle. Among animals, the size of a mitochondrial DNA molecule ranges from 14 to 18 kb. Mitochondrial DNA in plants is generally much larger, up to 100 kb. Plant chloroplast

DNA is more uniform in size than mitochondrial DNA, with a range of 130 to 200 kb.

On the basis of size alone, some kind of packaging of organelle DNA is necessary. For example, the mitochondrial DNA in human cells is a circular molecule of 16 kb. Fully extended, it would have a circumference about as large as that of the mitochondrion itself. From their bacterial origin, you might expect organelle DNA to be packaged as a nucleoid rather than as a chromosome, and indeed it is. However, the structures of the nucleoid in mitochondria and chloroplasts differ from each other, and they also differ from those in free-living bacteria.

#### Self-Assessment Questions

10. What are the different mechanisms by which bacterial cells and eukaryotic cells package their DNA?
11. Draw a nucleosome, indicating the positions of DNA and proteins.
12. What are “homologous chromosomes”? What technique could you use to show their similarity?

## 13.5 VIRUSES AND VIRAL GENOMES

Now we discuss viral genomes, but not because they are particularly complex. Viral genomes are actually rather small and compact with little or no repetitive DNA, and their sequences are relatively easy to assemble, as we have seen in [Fig. 13.7](#) for HIV. What sets viral genomes apart from those of cellular organisms are the types of nucleic acid that make up their genomes and the manner in which these genomes are replicated in the infected cells. In their nucleic-acid composition and manner of replication, viral genomes are far more diverse than the genomes of cellular organisms: all cellular organisms have genomes of double-stranded DNA that replicate by means of the processes described in [Chapter 12](#). This is not so with viruses. Furthermore, whereas biologists classify cellular organisms according to their degree of evolutionary relatedness, they classify viruses based on their type of genome and mode of replication.

We mostly think of viruses as causing disease, and indeed they do. Familiar examples include influenza (“flu”), polio, and HIV. In some cases, they cause cancer ([Case 2: Cancer](#)). In fact, the term “virus” comes from the Latin for “poison.” Yet viruses play other roles, too. Some viruses transfer genetic material from one cell to another. This process is called horizontal gene transfer to distinguish it from parent-to-offspring (vertical) gene transfer. Horizontal gene transfer has played a major role in the evolution of bacterial and archaeal genomes, as well as in the origin and spread of antibiotic resistance genes ([Chapter 24](#)). Molecular biologists have learned to make use of this

ability of viruses to deliver genes into cells.

In this section, we focus on viral diversity with an emphasis on viral genomes. Thousands of viruses have been described in detail, and probably millions more have yet to be discovered. It has been estimated that life on Earth is host to  $10^{31}$  virus particles—ten hundred thousand million more virus particles than grains of sand! Most of these viruses infect bacteria, archaeons, and unicellular eukaryotes, and they are especially abundant in the ocean ( $10^{11}$  viruses per liter). Viruses are small, consisting of little more than a genome in a package, and they can reproduce only by hijacking host-cell functions, but as a group they have had amazing evolutionary success.

## Viruses can be classified by their genomes.

The genomes of viruses are diverse. Some genomes are composed of RNA and others of DNA. Some are single stranded, others are double stranded, and still others have both single- and double-stranded regions. Some are circular and others are made up of a single piece or multiple linear pieces of DNA (called linear and segmented genomes, respectively).

Unlike forms of cellular life, there is no evidence that all viruses share a single common ancestor. Different types of virus may have evolved independently more than once. Because classification of viruses based on evolutionary relatedness is not possible, other criteria are necessary. One of the most useful classifications is the type of nucleic acid the virus contains and how the messenger RNA, which

produces viral proteins, is synthesized. The classification is called the Baltimore system, which was named after David Baltimore, who devised it.

According to the Baltimore system, there are seven major groups of viruses, designated I–VII, as shown in [Fig. 13.17](#). These groups are largely based on aspects of their nucleic acid. Viral genomes can be double-stranded DNA, double-stranded RNA, partially double-stranded and partially single-stranded, or single-stranded RNA or DNA with a positive (+) or negative (–) sense. The sense of a nucleic acid molecule is positive if its sequence is the same as the sequence of the mRNA that is used for protein synthesis, and negative if it is the complementary sequence. An example of a (+)RNA virus (Group IV) is the Zika virus, which recently invaded South and Central America from Africa and is inexorably spreading northward into the United States. Zika is associated with severe neurological abnormalities in the fetuses of women who were infected when pregnant.

FIG. 13.17 The Baltimore system of virus classification. This system classifies viruses by type of nucleic acid and the way mRNA is produced.

---

In a similar way that (+) and (–) RNA strands are defined in RNA viruses, a virus whose genome is (+)DNA strand has the same sequence as the mRNA, and one whose genome consists of a (–)DNA strand has the complementary sequence (except that U in RNA is replaced with T in DNA). Because mRNA is synthesized from a DNA template, it is the (–)DNA strand that is used for mRNA synthesis ([Chapter 3](#)).

Viruses categorized in Groups VI and VII have a single-stranded RNA genome and synthesize mRNA by the enzyme reverse transcriptase. [Reverse transcriptase](#) is an RNA-dependent DNA polymerase that uses a single-stranded RNA as a template to synthesize a complementary DNA strand ([Fig. 13.17](#)). The reverse transcriptase then displaces the RNA template and replicates the DNA strand to produce a double-stranded DNA molecule that can be incorporated into the host genome. In synthesizing DNA from an RNA template, the enzyme reverses the usual flow of genetic information from DNA to RNA. This capability is so unusual and was so unexpected that many molecular biologists at first doubted whether such an enzyme could exist. Finally, the enzyme was purified and its properties verified, for which its discoverers, Howard Temin and David Baltimore, were awarded the Nobel Prize in Physiology or Medicine in 1975, which was shared with Renato Dulbecco.

As we saw earlier, genome size varies greatly among different viruses. RNA viral genomes tend to be smaller than DNA viral genomes. Most eukaryotic viruses that have RNA genomes and most

plant viruses, including tobacco mosaic virus, are in Group IV. Among bacterial and archaeal viruses, most genomes consist of double-stranded DNA.

## The host range of a virus is determined by viral and host surface proteins.

Although viruses show great diversity in their nucleic-acid composition and manner of replication, they all consist of some type of nucleic acid, a capsid, and sometimes a lipid **envelope** ([Chapter 1](#)). Viruses can reproduce only by infecting living cells and exploiting the cell's metabolism and protein synthesis to produce more viruses. Most viruses are tiny—some hardly larger than a ribosome—measuring 25–30 nm in diameter. Roughly speaking, the average size of a virus, relative to that of the host cell it infects, may be compared to the size of an average person relative to that of a commercial airliner.

All known cells and organisms are susceptible to viral infection, including bacteria, archaeons, and eukaryotes. A cell in which viral reproduction occurs is called a **host cell**. Some viruses kill the host cell; others do not. Although viruses can infect all types of living organism, a given virus can infect only certain species or types of cell. At one extreme, a virus can infect just a single species. Smallpox, which infects only humans, is a good example. In cases like this, we say that the virus has a narrow host range. For other viruses, the host range can be broad. For example, rabies infects many different types of mammal, including squirrels, dogs, and humans. Similarly, tobacco mosaic virus, a plant virus, infects more than 100 different species of plants ([Fig. 13.18](#)). No matter how broad the host range, however,

plant viruses cannot infect bacteria or animals, and bacterial viruses cannot infect plants or animals.

*Courtesy H. D. Shew; Reproduced, by permission, from Shew, H. D., and Lucas, G. B., eds. 1991. Compendium of Tobacco Diseases. American Phytopathological Society, St. Paul, MN.*

FIG. 13.18 A plant infected by tobacco mosaic virus.

Host specificity results from the way that viruses gain entry into cells. Proteins on the surface of the capsid or envelope (if present) bind to proteins on the surface of host cells. These proteins interact in a specific manner, so the presence of the host protein on the cell surface determines which cells a virus can infect. For example, a protein on the surface of the HIV envelope called gp120 (encoded by the *env* gene; see [Fig. 13.7](#)) binds to a protein called CD4 on the surface of certain immune cells ([Chapter 41](#)), so HIV infects these cells but not other cells.

Following attachment, the virus gains entry into the cell, where it can replicate using the host cell machinery to make new viruses. In some cases, the viral genome integrates into the host cell genome ([Chapter 18](#)).

The host range of a virus can change because of mutation and other mechanisms ([Chapter 41](#)). For example, avian, or bird, flu is a type of influenza virus that was once restricted primarily to birds but now can infect humans. The first reported case in humans was in 1996, and the disease has since spread widely. Similarly, HIV once infected only nonhuman primates, but its host range expanded in the twentieth century to include humans. Canine distemper virus, which infects dogs, expanded its host range in the early 1990s, leading to the infection and death of lions in Tanzania.

## Viruses have diverse sizes and shapes.

Viruses show a wide variety of shapes and sizes, which are determined in some cases by the type of genome they carry. Three examples are shown in [Fig. 13.19](#). T4 virus ([Fig. 13.19a](#)) infects cells of the bacterium *Escherichia coli*. Viruses that infect bacterial cells are called [bacteriophages](#), which literally means “bacteria eaters.” The T4 bacteriophage has a complex structure that includes a head composed of protein surrounding a molecule of double-stranded DNA, a tail, and tail fibers. In infecting a host cell, the T4 tail fibers attach to the surface, and the DNA and some proteins are injected into the cell through the tail.

Sources: a. Dept. of Microbiology, Biozentrum/Getty Images; b. Biology Pics/Science Source; c. BSIP/Science Source.

**FIG. 13.19 Virus structures.** Viruses come in a variety of shapes, including (a) the head-and-tail structure of a bacteriophage, (b) the helical shape of tobacco mosaic virus, and (c) the icosahedral shape of adenovirus.

Most viruses are not structurally so complex. Consider the tobacco mosaic virus, which infects plants (see [Fig. 13.18](#)). It has helical shape formed by the arrangement of protein subunits entwined with a molecule of single-stranded RNA ([Fig. 13.19b](#)). Tobacco mosaic virus was the first virus discovered. It was revealed in experiments showing that the infectious agent causing brown spots and discoloration of tobacco leaves was so small that it could pass through the pores of filters that could trap even the smallest bacterial cells.

Many viruses have an approximately spherical shape formed from polygons of protein subunits that come together at their edges to form a polyhedral capsid. Among the most common polyhedral shapes is an icosahedron, which has 20 identical triangular faces. The example in [Fig. 13.19c](#) is adenovirus, a common cause of upper respiratory infections in humans. Many viruses that infect eukaryotic cells, such as adenovirus, are surrounded by a glycoprotein envelope composed of a lipid bilayer with embedded proteins and glycoproteins that recognize

and attach to host cell receptors.

The genome of a virus contains the genetic information needed to specify all the structural components of the virus. Progeny virus particles are formed according to **molecular self-assembly**: when the viral components are present in the proper relative amounts and under the right conditions, the components interact spontaneously to assemble themselves into the mature virus particle.

Tobacco mosaic virus illustrates the process of self-assembly. In the earliest stages, the coat-protein monomers assemble into two circular layers and form a cylindrical disk. This disk binds with the RNA genome, and the combined structure forms the substrate for polymerization of all the other protein monomers into a helical filament that incorporates the rest of the RNA as the filament grows (**Fig. 13.20**). The mature virus particle consists of 2130 protein monomers and 1 single-stranded RNA molecule of 6400 ribonucleotides.

FIG. 13.20 Tobacco mosaic virus. The protein and RNA components assemble themselves inside a cell.

Self-Assessment Question

13. What are the steps necessary to synthesize mRNA from each of the following: double-stranded DNA, single-stranded (+)DNA, single-stranded (−)DNA, single-stranded (+)RNA, and single-stranded (−)RNA?

## CORE CONCEPTS SUMMARY

**13.1 GENOME SEQUENCING:** A genome is the genetic material of a cell, organism, organelle, or virus, and its sequence is the order of bases along the DNA or (in some viruses) RNA.

The sequence of an organism's genome can be determined by breaking the genome into small fragments, sequencing these fragments, and then putting the sequences together at their overlaps. [page 282](#)

Sequences that are repeated in the genome can make sequence assembly difficult. [page 282](#)

**13.2 GENOME ANNOTATION:** Researchers annotate genome sequences to identify genes and other functional elements.

Genome annotation is the process by which the types and locations of the different kinds of sequences, such as protein-coding genes, are identified. [page 284](#)

Genome annotation sometimes involves scanning the DNA sequence for characteristic sequence motifs. [page 285](#)

Comparison of DNA sequences with messenger RNA sequences reveals the intron–exon structure of protein-coding genes. [page 286](#)

By comparing annotated genomes of different organisms, we can gain insight into their ancestry and evolution. [page 287](#)

The annotated HIV genome shows it is a retrovirus, and it contains the genes *gag*, *pol*, and *env*. [page 287](#)

### 13.3 GENES, GENOMES, AND ORGANISMAL COMPLEXITY:

The number of genes in a genome and the size of a genome do not correlate well with the complexity of an organism.

The C-value paradox describes the observation that the size of a genome (measured by its C-value) does not correlate with an organism's complexity. [page 288](#)

In eukaryotes, the C-value paradox can be explained by differences in the amount of noncoding DNA, including repetitive sequences and transposons. Some genomes have a lot of noncoding DNA; others do not. [page 289](#)

**13.4 ORGANIZATION OF GENOMES:** The orderly packaging of DNA allows it to carry out its functions and fit inside the cell.

Bacteria package their circular DNA in a structure called a nucleoid. [page 292](#)

Eukaryotic cells package their DNA into linear chromosomes. [page 293](#)

DNA in eukaryotes is wound around groups of histone proteins called nucleosomes to form a 10-nm fiber, which in turn coils to form higher-order structures, such as the 30-nm fiber. [page 293](#)

Diploid organisms have two copies of each chromosome, called homologous chromosomes. [page 294](#)

Humans have 23 pairs of chromosomes, including the X and Y sex-chromosome pair. Females are XX and males are XY. [page 294](#)

The genomes of mitochondria and chloroplasts are organized into nucleoids that resemble, but are distinct from, those of bacteria.

[page 295](#)

**13.5 VIRUSES AND VIRAL GENOMES:** Viruses have diverse genomes, but all require a host cell to replicate.

Viruses can be classified by the Baltimore system, which defines seven groups on the basis of type of nucleic acid and the way mRNA is synthesized. [page 296](#)

Viruses can infect all types of organism, but a given virus can infect only some types of cell. [page 297](#)

The host range of a virus is determined by proteins on viral and host cells. [page 297](#)

Viruses have diverse shapes, including head-and-tail, helical, and icosahedral. [page 298](#)

Viruses are capable of molecular self-assembly under the appropriate conditions. [page 298](#)

## CHAPTER 14 Mutation and Genetic Variation

Tetra Images/Getty Images

---

## CORE CONCEPTS

**14.1 GENOTYPE AND PHENOTYPE:** The genetic makeup of a cell or organism is its genotype, and an observable characteristic is its phenotype.

**14.2 THE NATURE OF MUTATIONS:** Mutations are very rare for any given nucleotide and occur randomly without regard to the needs of an organism.

**14.3 SMALL-SCALE MUTATIONS:** Small-scale mutations include point mutations, insertions and deletions, and movement of transposable elements.

**14.4 CHROMOSOMAL MUTATIONS:** Chromosomal mutations involve large regions of one or more chromosomes.

**14.5 DNA DAMAGE AND REPAIR:** Mutations occur spontaneously and are induced by mutagens, but most DNA damage is repaired.

---

The sequencing of the human genome was a great step forward in our understanding of ourselves. However, as we saw in the previous chapter, it is an oversimplification to speak of *the* human genome. Almost all species have abundant amounts of **genetic variation**, which refers to the genetic differences that exist among individuals in a population at a particular time. Genetic variation accounts in part for the physical differences we see among individuals, such as differences in hair color, eye color, and height. And, on a much larger scale, genetic differences among species result in the diversity of organisms on this planet, from bacteria to blue whales.

Variation among different individuals' genomes arise from

**mutations.** Any heritable change in the nucleotide sequence of DNA is a mutation. A change might be a substitution of one base for another, a small deletion or insertion of a few bases, or a larger alteration affecting a segment of a chromosome. By “heritable,” we mean that the mutation persists through DNA replication and is transmitted during cell division (meiotic cell division, mitotic cell division, or binary fission). Most mistakes in DNA replication or chemical damage to DNA are immediately repaired by specialized enzymes in the cell. Some, however, escape these repair mechanisms and are transmitted from parental cell to daughter cell.

In this chapter, we examine some of the basic principles of mutation and genetic variation: different types of mutation, how and when they occur, and how errors in DNA replication and various types of DNA damage are repaired. In [Chapters 15](#) and [16](#), we look at how this variation is inherited from one generation to the next.

# 14.1 GENOTYPE AND PHENOTYPE

A mutation occurs in an individual cell at a particular point in time. Through evolution ([Chapters 1](#) and [20](#)), the proportion of individuals in a population carrying this mutation may increase or decrease. Therefore, if we look at any present-day population of organisms, such as the human population, we will find that it harbors lots of genetic differences, all of which resulted from mutations that occurred sometime in the past.

We tend to think of mutations as something negative or harmful because, in everyday language, the term “mutant” suggests something abnormal. In reality, because mutations result in genetic variation among individuals, we are all “mutants” that differ from one another in our DNA. Although it is true that many mutations are harmful, other mutations have negligible effects on the organism, and a precious few are beneficial. Without beneficial mutations, evolution would not be possible. Mutations generate the occasional favorable variants that allow organisms to evolve and become adapted to their environment over time ([Chapter 20](#)).

In the human population, you can observe the effects of common genetic differences or mutations by looking at the people around you. They differ in height, weight, facial features, skin color, eye color, hair color, hair texture, and many other ways. These traits differ in part because of genetic variation, and in part because of the environment. Weight is affected by diet, for example, and skin color by exposure to

sunlight.

## Genotype is the genetic makeup of a cell or organism, and the phenotype is its observed characteristics.

The genetic makeup of a cell or organism constitutes its **genotype**. A population with a gene pool that has many variants in many different genes will consist of organisms with many different genotypes. For example, any two human genomes are likely to differ from each other at about 3 million nucleotide sites, or about one difference per thousand nucleotides across the genome. In other words, we differ from one person to the next but only in a very small fraction of nucleotides.

Mutations are the ultimate source of differences among genotypes. If we consider any present-day population of organisms, we will find that some genetic differences are especially common. Geneticists use the term **polymorphism** to refer to any genetic difference among individuals that is present in multiple individuals in a population. For example, if some people have an A—T base pair at a particular site in the genome, but others have a G—C base pair at the same site, this difference is a polymorphism. The polymorphism is the result of a mutation that occurred in the past, spread through the population, and is now shared among a subset of individuals in a population.

The different forms of any gene are called **alleles**, and they correspond to different DNA sequences (polymorphisms) in the genes.

An individual who inherits the same allele of a gene from each parent is [homozygous](#). By contrast, an individual who inherits a different allele of a gene from each parent is [heterozygous](#).

An individual's [phenotype](#) is the individual's observable characteristics or traits, such as height, weight, eye color, and so forth. It may be visible, as in these characteristics, or it may be seen in the development, physiology, or behavior of a cell or organism. For example, color blindness and lactose intolerance are phenotypes. The phenotype results in part from the genotype. For example, a genotype with a mutation that affects expression of an enzyme that normally metabolizes lactose can lead to the phenotype of lactose intolerance. However, the environment also commonly plays an important role in the expression of the genotype, so it is most accurate to say that a phenotype results from an interaction between the genotype and the environment. These genotype–environment interactions are discussed in [Chapter 18](#).

## Some genetic differences are harmful.

Mutations affect not only observable characteristics of an organism, but also the probability that an organism is able to survive and reproduce in a particular environment. Viewed in this way, mutations can be harmful, neutral, or even beneficial. Harmful mutations are often eliminated in one or a few generations because they decrease the survival or reproduction of the individuals that carry them. Less harmful mutations may persist in a population.

For example, many polymorphisms increase susceptibility to

particular diseases but do not cause the disease themselves. One such polymorphism increases the risk of emphysema, a condition marked by loss of lung tissue. Patients with emphysema suffer from shortness of breath even when at rest, a wheezy cough, and increased blood pressure in the arteries of the lungs. Without proper treatment, the disease progresses to respiratory failure or congestive heart failure, and eventually to death. Onset of the disease usually occurs in middle age, and the life-span of affected individuals is shortened by 10 to 30 years depending on the effect of treatment.

Emphysema results from reduced activity of the enzyme alpha-1 antitrypsin ( $\alpha$ 1AT). The main function of  $\alpha$ 1AT is to inhibit another enzyme, known as elastase, which breaks down the connective-tissue protein elastin in lungs ([Fig. 14.1a](#)). The elasticity of the lung, which allows normal breathing, requires a balance between the production and the breakdown of elastin. Too-rapid breakdown by elastase is normally prevented by the inhibition of elastase by  $\alpha$ 1AT.

FIG. 14.1 A harmful mutation. (a) The enzyme alpha-1 antitrypsin ( $\alpha$ 1AT) normally inhibits the activity of elastase, which breaks down elastin in the lung. (b)

A mutation in  $\alpha 1AT$  called *PiZ* is harmful because it reduces  $\alpha 1AT$  activity and leads to increased risk of emphysema.

Although approximately 80% of all cases of emphysema can be traced to cigarette smoking, in some affected individuals genetics plays a role. An individual's risk of emphysema is significantly increased by inheriting a mutation in the gene that encodes  $\alpha 1AT$ . The mutation results in an enzyme with reduced activity ([Fig. 14.1b](#)). Among the many different alleles of this gene, a mutant allele denoted *PiZ* is particularly common in populations of European descent. Any mutation that increases the risk of disease in an individual is known as a **genetic risk factor** for that disease. A risk factor does not *cause* the disease, but rather makes the disease *more likely* to occur.

## Some genetic differences are neutral.

Mutations that have negligible effects on survival or reproduction are considered **neutral**. Many mutations are neutral because they occur in noncoding DNA. Neutral mutations are therefore especially likely to occur in organisms with large genomes and abundant noncoding DNA ([Chapter 13](#)).

One example in human populations is the taster phenotype associated with perception of a bitter taste from certain chemicals, including phenylthiocarbamide (PTC). The ability to taste PTC is due largely, but not exclusively, to alleles of a single gene called *TAS2R38* that encodes a taste receptor in the tongue. Humans who are homozygous for an allele of this gene called *PAV* are almost all tasters, while most humans with at least one copy of another allele called *AVI*

are almost all nontasters.

The ability to taste PTC is a polymorphism that differs in frequency among populations. Around the world, the frequency of nontasters varies from a low of 3% in West Africa to a high of 40% in India. Tasters often perceive a disagreeable bitterness in broccoli, cauliflower, kale, Brussels sprouts, and related vegetables.

## A few genetic differences are beneficial.

While many mutations are neutral and many others are harmful, a few mutations are beneficial. In human populations, beneficial mutations are often discovered through their effects in protecting against infectious disease. Here we consider a mutation that protects against acquired immune deficiency syndrome (AIDS), which is caused by the human immunodeficiency virus (HIV).

A glycoprotein on the surface of HIV interacts with a cell-surface receptor called CD4 to gain entry into immune cells called T cells ([Fig. 14.2](#)). Interaction with CD4 alone, however, does not enable the virus to infect the T cell. The HIV surface glycoprotein must also interact with another receptor on the T cell, which is denoted CCR5 (the red surface protein in [Fig. 14.2](#)), in the early stages of infection. The normal function of CCR5 is to bind certain small secreted proteins that promote tissue inflammation in response to infection. But because CCR5 is also an HIV receptor, cells lacking CCR5 are more difficult to invade.

FIG. 14.2 HIV infection of T cells. HIV gains entry into a T cell by interacting with a CD4 protein and a CCR5 receptor on the surface of T cells.

A beneficial effect of a particular mutation in the *CCR5* gene was discovered in studies focusing on HIV-infected patients whose infection had not progressed to full-blown AIDS after 10 years or more. The protective allele is denoted as  $\Delta 32$  (*delta 32*) because the mutation is a deletion that removes 32 base pairs in the coding sequence of the *CCR5* gene ([Fig. 14.3](#)). The mutant protein that results from this deletion is completely inactive.

FIG. 14.3 A beneficial mutation in the human population. Mutant *CCR5* has a 32-nucleotide deletion that results in defective CCR5 protein and, therefore, slows the progression of HIV to AIDS.

The effect of the  $\Delta 32$  allele is pronounced. In individuals with the homozygous  $\Delta 32/\Delta 32$  genotype, HIV progression to AIDS is rarely observed. There is some protective effect from this mutation even in individuals with heterozygous  $\Delta 32$  genotypes, in whom progression to AIDS is delayed by an average of about 2 years after infection by HIV.

## The effect of a mutation may depend on the genotype and environment.

Whether a mutation is harmful, neutral, or beneficial often depends on factors other than the mutation itself. For example, some mutations can be harmful in some environments, but are neutral or even beneficial in others. Let's consider mutations in the human DNA sequence coding for  $\beta$ -(beta-)globin, a subunit of the protein hemoglobin, which carries oxygen in red blood cells. We will return to mutations in  $\beta$ -globin several times in this chapter. [Fig. 14.4](#) shows three alleles of the  $\beta$ -globin gene: A, S, and C. These three alleles are relatively common in certain African populations.

FIG. 14.4 Three alleles of the gene encoding  $\beta$ -globin, a subunit of hemoglobin. Both the S allele and the C allele are associated with increased resistance to malaria.

The most frequent allele is the A allele, which has a GAG codon in the position indicated. This codon translates to glutamic acid (Glu) in the resulting polypeptide. The S and C alleles contain mutations that change the Glu found in the A allele to valine (Val) or lysine (Lys), respectively (red nucleotides in [Fig. 14.4](#)). Although in each case only one amino acid of the  $\beta$ -globin protein is affected, this change can have a dramatic effect on the function of the protein, since the amino acid sequence determines how a protein folds, and protein folding in turn determines the protein's function ([Chapter 4](#)).

For the hemoglobin A, S, and C alleles, there are three possible homozygous genotypes: AA, SS, and CC. The first letter or symbol in each pair indicates the allele inherited from one parent, and the second indicates the allele inherited from the other parent. By convention,

alleles and genotypes are designated by italic letters.

There are also three possible heterozygous genotypes: *AS*, *AC*, and *SC*. While each individual can have only two alleles of a gene, many more alleles can exist in an entire population. In this example, a person can be homozygous, with two identical alleles, or heterozygous, with two different alleles, though there are three different alleles in the population.

What are the effects of these mutations? Are they beneficial, harmful, or neutral? The short answer is, it depends. Let's consider the *S* allele. Homozygous *SS* individuals have sickle-cell anemia. In this condition, the hemoglobin molecules tend to bind together, or polymerize, when exposed to lower than normal levels of oxygen. The polymerization of hemoglobin causes the cell to change from its normal oval shape into the shape of a half-moon, or "sickle." In this form, the red blood cell is unable to carry the normal amount of oxygen. In addition, the sickled cells tend to block small capillaries, interrupting the blood supply to vital tissues and organs and resulting in severe pain. In the absence of proper medical care, patients with sickle-cell anemia usually die before adulthood.

Heterozygous *AS* individuals have only a mild anemia called the sickle-cell trait. Furthermore, in Africa, where malaria is widespread, being a heterozygote is actually beneficial because it provides some protection against malaria.

This example illustrates two important principles about the connection between genotype and phenotype. First, the effect of a

mutation often depends on whether the mutation is homozygous or heterozygous. In areas with malaria, the *S* allele is harmful as a homozygous genotype, but is beneficial as a heterozygous genotype. Second, the effect of a mutation may depend on the environment. The *S* allele, when heterozygous, is beneficial only in malarial-prone regions, where it offers protection from the disease that outweighs its other effects. In areas without malaria, it is harmful.

What about the *C* allele? Heterozygous *AC* individuals have partial protection against malaria, and homozygous *CC* individuals are not only more protected from malaria but also have a very mild anemia that usually needs no medical treatment. As with the *S* allele, the phenotype of the *C* allele depends on whether the individual is heterozygous or homozygous for the allele and whether malaria is present or absent.

#### Self-Assessment Questions

1. What determines a genotype? What determines a phenotype?
2. With regard to mutations, what is meant by the terms “harmful,” “beneficial,” and “neutral”? Why it is sometimes an oversimplification to consider a mutation as harmful, beneficial, or neutral?
3. A mutation arises in a bacterium that confers antibiotic resistance. Is this mutation harmful, beneficial, or neutral?

## 14.2 THE NATURE OF MUTATIONS

Mutations result from mistakes in DNA replication or from unrepaired damage to DNA. The damage may result from reactive molecules produced in the normal course of metabolism, chemicals in the environment, or radiation of various types, including X-rays and ultraviolet light. Most genomes also contain DNA sequences that can “jump” from one position to another in the genome, and their insertion into or near genes is a source of mutation.

Most mutations are **spontaneous**, occurring by chance in the absence of any assignable cause. They occur randomly, unconnected to an organism’s needs: it makes no difference whether a given mutation would benefit the organism. Whether a favorable mutation does or does not occur is purely a matter of chance. This key principle, that mutations are spontaneous and random, is the focus of the following section.

**Mutation of individual nucleotides is rare, but mutation across the genome is common.**

Later in this chapter, we’ll distinguish among several different types of mutations. For now, let’s consider the most common mutation: the substitution of one nucleotide for a different nucleotide. Nucleotide-substitution mutations are nevertheless relatively rare, and their rate of occurrence differs among organisms. **Fig. 14.5a** compares the rates of

newly arising mutations in a given base pair in a single round of replication in viruses and several types of organisms. As seen in the graph, the nucleotide mutation rates for different organisms range across almost eight orders of magnitude. Differences among organisms in the fidelity of replication and various other repair mechanisms account for much of this variation. For instance, polymerases in RNA viruses and retroviruses have no proofreading function, whereas in the cellular organisms in [Fig. 14.5a](#), only one nucleotide in every 10 billion is mistakenly substituted for another and slips through the proofreading process.

FIG. 14.5 Mutation rates. (a) Rate per nucleotide per round of replication. (b) Rate per genome per generation. Data from J. W. Drake, B. Charlesworth, D. Charlesworth, J. F. Crow, 1998, "Rates of Spontaneous Mutation," *Genetics* 148:1667–1686.

However, averaging across an entire genome conceals many details. Certain nucleotides are especially prone to mutation and can exhibit rates of mutation that are greater than the average by a factor of 10 or

more. Sites in the genome that are especially mutable are called **hotspots**. The rate of mutation also depends on whether the cells are **germ cells** (haploid gametes and the diploid cells that give rise to them) or **somatic cells** (the other cells of the body). In mammals, the rate of mutation per nucleotide per replication is greater in somatic cells than in germ cells because DNA repair mechanisms are more efficient in germ cells.

While the rate of mutation per nucleotide per replication in most multicellular organisms is low, the rate of mutation in a whole organism depends on the size of the genome and the number of cell divisions per generation of the organism (**Fig. 14.5b**). A comparison of the two graphs in **Fig. 14.5** shows that, while humans have the lowest rate of mutation per nucleotide per replication (**Fig. 14.5a**), humans also have the highest *number* of mutations per genome per generation (**Fig. 14.5b**). This seeming paradox arises because humans have a large genome and undergo many cell divisions over their lifetime, providing more opportunities for mutations to occur.

In humans, the average number of newly arising nucleotide-substitution mutations per genome in one generation is about 30, or about 60 per diploid zygote. Approximately 80% of the newly arising mutations in a zygote come from the father. The main reason is that, in a human male at age 30, the diploid germ cells have gone through about 400 cycles of DNA replication and cell division before meiosis takes place to form sperm cells, compared with about 30 cycles in females to form oocytes (**Chapter 11**). Moreover, whereas the number of newly arising mutations from the mother remains approximately

constant with the mother's age, the number of newly arising mutations from the father increases with age. Sperm from men of age 40 contain about twice as many newly arising mutations as sperm from men of age 20.

This large number of mutations is tolerable only because more than 90% of the nucleotides in the genome seem free to vary without harmful consequences. A mere 2.5% of the human genome codes for protein ([Chapter 13](#)).

## Only germ-line mutations are transmitted to progeny.

Which is more important—the rate of mutations per nucleotide per replication or the number of mutations per genome per generation? The answer depends on whether we are interested in the cells of individual organisms or the transmission of mutations from parent to offspring. Mutations can take place in any type of cell. Those that occur in eggs and sperm and the cells that give rise to them are called [germ-line mutations](#), and for mutations in these reproductive cells, researchers are most interested in the number of mutations per genome per generation. Germ-line mutations are important to the evolutionary process because, as they are passed from one generation to the next, they may eventually come to be present in many individuals descended from the original carrier.

In contrast, mutations in nonreproductive cells are called [somatic mutations](#), and for these mutations, what matters is the rate of mutations per nucleotide per replication. Although somatic mutations

are not transmitted to future generations, they are transmitted to daughter cells in mitotic cell divisions ([Chapter 11](#)). Hence, a somatic mutation affects not only the cell in which it occurs, but also all the cells that descend from it. The areas of different colors or patterns that appear in “sectored” flowers, valued as ornamental plants ([Fig. 14.6](#)), are usually due to somatic mutations in flower-color genes. A mutation in a flower-color gene occurs in one cell, and as the cell replicates during development of the flower, all its descendants in the cell lineage—the generations of cells that originate from a single ancestral cell—carry that mutation, producing a sector with altered coloration.

Source: Courtesy Atsushi Hoshino, National Institute for Basic Biology, Japan.

**FIG. 14.6 Somatic mutation.** Somatic mutations in the Japanese morning glory (*Ipomoea nil*) in cell lineages that differ in their ability to make purple pigment cause sectors of different pigmentation in the flower.

Most cancers result from mutations in somatic cells ([Chapter 11](#)). In some cases, the mutation increases the activity of a gene that promotes

cell growth and division, whereas in other cases it decreases the activity of a gene that restricts cell growth and division. In either event, the mutant cell and its descendants escape from one of the normal control processes. Fortunately, a single somatic mutation is usually not sufficient to cause cancer—usually two or three or more mutations in different genes are required to derail control of normal cell division so extensively that cancer results.

In some cancers, several mutations must occur sequentially in a single cell lineage for the disease to become manifest. [Fig. 14.7](#) shows three key mutations that have been implicated in the origin of one type of invasive colon cancer: *p53*, *Ras*, and *APC*. Each mutation occurs randomly, but if by chance a mutation in the *Ras* gene occurs in a cell in which the *APC* gene is already mutated, that cell's progeny forms a polyp. Another chance mutation in the same cell lineage, which now carries mutations in both the *APC* and *Ras* genes, could lead to malignant cancer. Normally, the occurrence of multiple mutations in a single cell lineage is rare, but in people exposed to chemicals that cause mutations or who carry mutations in DNA repair processes, multiple mutations in a single cell lineage are more likely to occur, and so the risk of cancer is increased.

FIG. 14.7 Three somatic mutations implicated in the origin of invasive colon cancer. These mutations must occur in the same cell lineage for cancer to develop.

## CASE 3 YOUR PERSONAL GENOME: YOU, FROM A TO

T

# What can your personal genome tell you about your genetic risk factors for cancer?

Cancer usually occurs because of a series of mutations that occur sequentially in a single lineage of somatic cells, as illustrated for colon cancer in [Fig. 14.7](#). In most individuals with cancer, all the sequential mutations that cause the cancer are spontaneous mutations that take place in somatic cells. They are not transmitted through the germ line, so there is little or no increased risk of cancer in the offspring. In some families, however, a germ-line mutation in one of the genes implicated in cancer is transmitted from parents to their children. In any child who inherits the mutation, all cells in the body contain the defective gene, and hence the cells already have taken one of the mutational steps that lead to cancer.

For colon cancer, the major genetic risk factors are mutations in *APC*, *Ras*, and *p53*. For breast cancer, the major genetic risk factors are mutations in the *BRCA1* and *BRCA2* genes. For these genes, each is a risk factor because when it is mutated, fewer additional mutations are needed to bring about tumor growth.

The DNA sequence of each of our personal genomes can reveal the genetic risk factors that each of us carries, not only for cancer but for many other diseases as well. Not all genetic risk factors are known for all diseases, but many genetic risk factors are already known for a large number of common diseases, including high blood pressure, diabetes, inflammatory bowel disease, age-related macular degeneration,

Alzheimer's disease, and many forms of cancer.

Our personal genomes can identify only genetic risk factors, however. In many cases, disease risk is substantially increased by environmental risk factors as well, especially lifestyle choices. While there are genetic risk factors for lung cancer, for example, the single biggest environmental risk factor is tobacco smoking. For skin cancer, the greatest environmental risk factor is exposure to the damaging ultraviolet rays in sunlight or in the sunlamps used in tanning beds. For heart disease, the key environmental risk factors are smoking, lack of physical activity, and obesity. For diabetes, it is an unhealthy diet.

For breast cancer, the environmental risk factors include certain forms of hormone therapy, lack of physical activity, and use of alcohol. While we may not be able to do much about the genetic risk factors for any of these conditions, knowing that we have them may make us more careful about the lifestyle choices that we make.

## Mutations are random with regard to an organism's needs.

Consider the following experiment: an antibiotic is added to a liquid culture of bacterial cells that are growing and dividing. Most of the cells are killed, but a few survivors continue to grow and divide. These survivors are found to contain mutations that confer resistance to the antibiotic. This simple observation raises a profound question: were the antibiotic-resistant mutations already present before the antibiotic was added, implying that they arise spontaneously, or do the antibiotic-resistant mutations arise in response to the antibiotic?

These alternative hypotheses have deep implications for all of biology because they suggest two very different ways in which mutations might arise. The first suggests that mutations occur without regard to the needs of an organism. According to this hypothesis, the presence of the antibiotic in the experiment with bacterial cells does not direct or induce antibiotic resistance in the cells, but instead kills off all but the small number of preexisting antibiotic-resistant mutants, allowing them to flourish. The second hypothesis suggests that some sort of feedback occurs between the needs of an organism and the process of mutation, such that the environment directs specific mutations that are beneficial to the organism.

To distinguish between these two hypotheses, Joshua and Esther Lederberg in 1952 carried out a now-famous experiment, described in [Fig. 14.8](#). Bacterial cells were grown and formed colonies on agar plates in the absence of antibiotic. Then, using a technique called replica plating, the Lederbergs transferred these colonies to new plates containing antibiotic. Only bacteria that were resistant to the antibiotic grew on the new plates. Because replica plating preserved the physical arrangement of the colonies, the Lederbergs were able to go back to the original plate and identify the colony that produced the antibiotic-resistant colony on the replica plate. From that original colony, they were then able to isolate a pure culture of antibiotic-resistant bacteria.

#### HOW DO WE KNOW?

### FIG. 14.8

Do mutations occur randomly, or are they directed by the environment?

## BACKGROUND

Researchers have long observed that beneficial mutations tend to persist in environments where they are useful. For example, in the presence of antibiotics, bacterial populations become antibiotic resistant; in the presence of insecticides, insect populations become insecticide resistant.

## HYPOTHESIS

These observations lead to two hypotheses about how a mutation, such as one that confers antibiotic resistance to bacteria, might arise. The first suggests that mutations occur randomly in bacterial populations and over time become more common in the population in the presence of an antibiotic (which kills bacteria that do not have the mutation). In other words, they occur randomly with respect to the needs of an organism. The second hypothesis suggests that the environment, in this case the application of antibiotic, induces or directs mutations conferring antibiotic resistance.

## METHOD

To distinguish between these two hypotheses, Joshua and Esther Lederberg developed a technique called replica plating. In this technique, bacteria are grown on plates of a solid gel-like medium containing agar and nutrients, where they form colonies of cells ([Fig. 14.8a](#)). The cells in any one colony result from the division of a single original cell, so all individual bacteria in a single colony are genetically identical except for rare mutations that occur in the course of growth and division. Then a disk of sterilized velvet is pressed onto the plate. The velvet disk picks up cells from each colony and preserves in mirror image their geometrical positions on the plate. The velvet disk is pressed onto the surface of a fresh plate, transferring to the new plate some of the cells that originate from the colony on the first agar plate, in their original positions.

## EXPERIMENT AND RESULTS

First, the Lederbergs grew bacterial colonies on a master plate containing medium without antibiotic. Then, by replica plating, they transferred some cells from each colony to two plates ([Fig. 14.8b](#)). One plate contained medium without antibiotic. This first plate was the nonselective medium and served as the control; all cells were able to grow and form colonies on it. The second plate contained medium with antibiotic. This was the selective medium: only antibiotic-resistant cells multiplied and formed colonies on this second plate. It served as the experimental treatment.

Because replica plating preserves the arrangement of the colonies, the location of an antibiotic-resistant colony that grew on the selective medium revealed the location of its parental colony on the control plate. In the final step of the experiment, the Lederbergs went back to the parental colony and plated cultures of just the antibiotic-resistant parent colony, the location of which had been revealed on the selective medium experimental treatment plate ([Fig. 14.8c](#)).

## CONCLUSION

The Lederbergs' replica-plating experiments showed that antibiotic-resistant mutants can arise in the absence of antibiotic, because antibiotic-resistant cells were isolated in those experiments even though the parental cells on nonselective medium never came into contact with the antibiotic. Only the daughter cells carried over to selective medium by replica plating were exposed to the antibiotic. In the final step of the experiment, the Lederbergs were able to isolate pure colonies of antibiotic-resistant cells.

## FOLLOW-UP WORK

These results have been extended to other types of mutation and other organisms, demonstrating that mutations are random and not directed by the environment.

SOURCE Lederberg, J., and E. M. Lederberg. 1952. "Replica Plating and Indirect

In the Lederbergs’ experiments, isolating antibiotic-resistant bacteria from the original plate showed that the mutation for antibiotic resistance existed in the bacteria before they were ever exposed to antibiotic. This result supported the hypothesis that mutations occur spontaneously without regard to the needs of the organisms. The environment does not create specific mutations, but instead selects for them. The principle the Lederbergs demonstrated is true of all organisms so far examined.

#### Self-Assessment Questions

4. Mutations in which types of cell are most likely to contribute to evolutionary change in a population of organisms? Why?
5. What is the difference between the mutation rate for a given nucleotide and the mutation rate for a given cell?
6. If mutations occur at random with respect to an organism’s needs, how does a species become more adapted to its environment over time?

## 14.3 SMALL-SCALE MUTATIONS

At the molecular level, a mutation is a change in the nucleotide sequence of a genome. Such changes can be small, affecting one or a few bases, or large, affecting entire chromosomes. In this section, we consider the origin and effects of small-scale changes to the DNA sequence. While mutation provides the raw material that allows evolution to take place, it can play this role only because of an important feature of living systems: once a mutation has taken place in a gene, the mutant genome is replicated as faithfully as the nonmutant genome.

### Point mutations are changes in a single nucleotide.

Most DNA damage or errors in replication are immediately removed or corrected by specialized enzymes in the cell ([section 14.5](#)). We have already seen one type of DNA repair, the proofreading function of DNA polymerase during the process of replication, which acts to remove an incorrect nucleotide from the 3' end of the growing DNA strand (see [Fig. 12.7](#)). Damage that is corrected is not regarded as a mutation because the DNA sequence is immediately restored to its original state and the mutation is not replicated in the daughter DNA.

If a mutation in DNA is to be inherited through mitotic or meiotic cell divisions, it must escape correction by the DNA repair systems. The example in [Fig. 14.9](#) shows how a mutation incorporated during replication can become a permanent change to the genome. Recall that

in a double-stranded DNA molecule, the A's in one strand pair with T's in the other, and the G's in one strand pair with C's in the other. If, during replication, DNA polymerase mistakenly adds a G instead of a T (shown in red in [Fig. 14.9](#)) to a growing strand across from an A and its proofreading function does not correct the error, the result is a T—G mismatch in the double-stranded DNA. At the next replication, the G in the new template strand specifies a C in the daughter strand, with the result that the daughter DNA duplex has a perfectly matched C—G base pair. From this point forward, the DNA molecule containing the mutant C—G base pair will replicate as faithfully as the original molecule bearing the nonmutant T—A base pair. A mutation in which one base pair (in this example, T—A) is replaced by a different base pair (in this example, C—G) is called a nucleotide substitution or [point mutation](#).

FIG. 14.9 A point mutation. A point mutation is a change in a single nucleotide.

Point mutations are among the most common types of mutations in present-day genomes. As we saw earlier, common genetic differences in a population are called polymorphisms, so a difference between two sequences at a single nucleotide position in a DNA sequence is called a **single-nucleotide polymorphism** (abbreviated as **SNP** and pronounced “snip”). A SNP is the result of a point mutation that occurred sometime in the past and then increased in frequency so that many individuals in the population now carry it. For example, the differences among the A, S, and C alleles of the gene for  $\beta$ -globin are SNPs because they differ from one another at just one nucleotide site (see [Fig. 14.4](#)).

## The effect of a point mutation depends in part on where in the genome it occurs.

In many multicellular eukaryotes, including humans, the vast majority of DNA in the genome does not code for protein or for RNAs with known function ([Chapter 13](#)). Most of the sequences in noncoding DNA have no known function, which may explain why many point mutations in noncoding DNA have no detectable effects on the organism.

In contrast, point mutations in coding sequences do have predictable consequences in an organism. [Fig. 14.10](#) shows an example in the human DNA sequence coding for  $\beta$ -globin, a subunit of hemoglobin,

which we discussed in [section 14.1](#). [Fig. 14.10a](#) shows a small part of the nonmutant DNA sequence, transcription and translation of which results in incorporation of the amino acids Pro–Glu–Glu in the  $\beta$ -globin polypeptide.

FIG. 14.10 Synonymous and nonsynonymous mutations. Synonymous mutations do not change the amino acid sequence of the resulting protein. Nonsynonymous mutations change the amino acid sequence.

[Fig. 14.10b](#) shows an example of a neutral, or harmless, nucleotide substitution in this coding sequence. In this mutation, an A—T base pair (shown in red) is substituted for the normal G—C base pair. When transcribed into mRNA, the mutation changes the normal GAG codon into the mutant GAA codon. But GAG and GAA both code for the same amino acid, glutamic acid (Glu). In other words, they are synonymous codons, so the resulting amino acid sequences are the

same: Pro–Glu–Glu. Such mutations are called **synonymous (silent) mutations**. This example is typical in that the synonymous codons differ at their third position (the 3' end of the codon). A quick look at the genetic code (see [Table 4.1](#)) shows that most amino acids can be specified by synonymous codons, and that in most cases the synonymous codons differ in the identity of the nucleotide at the third position.

A point mutation in a coding sequence can sometimes have harmful effects on the organism. [Fig. 14.10c](#) shows such an example, in which a T—A base pair (shown in red) is substituted for the normal A—T base pair. The result is a change in the mRNA from GAG, which specifies Glu (glutamic acid), to GUG, which specifies Val (valine). The resulting protein therefore contains the amino acids Pro–Val–Glu instead of Pro–Glu–Glu. This is the *S* allele that we discussed earlier (see [Fig. 14.4](#)). As we saw, this single amino acid change affects the ability of hemoglobin to function normally. In this case, the nucleotide substitution results in an **amino acid replacement**. Point mutations that cause amino acid replacements are called **nonsynonymous (missense) mutations**.

[Fig. 14.11](#) shows a third way that a point mutation can affect a protein: a **nonsense mutation**, which creates a stop codon that terminates translation. A nonsense mutation nearly always has harmful effects. In [Fig. 14.11](#), the mutation creates a UAG codon in the mRNA. Because UAG is a translational stop codon, the resulting polypeptide terminates after Pro. Polypeptides that are truncated are nearly always nonfunctional, are unstable, and are quickly destroyed. Eukaryotic cells

have mechanisms to destroy most mRNA molecules that contain premature stop codons.

FIG. 14.11 A nonsense mutation. A nonsense mutation can change an amino acid to a stop codon, resulting in a shortened and unstable protein.

## Small insertions and deletions involve several nucleotides.

Another relatively common type of mutation is the deletion or insertion of a small number of nucleotides. In noncoding DNA, such mutations have little or no effect. In protein-coding regions, their effects depend on their size. A small deletion or insertion that is an exact multiple of three nucleotides results in a polypeptide with fewer (in the case of a deletion) or more (in the case of an insertion) amino acids as there are codons deleted or inserted. For example, a deletion of three nucleotides eliminates one amino acid, and an insertion of six nucleotides adds two amino acids.

The effects of a deletion of three nucleotides can be seen in cystic fibrosis. This disease is characterized by the production of abnormal secretions in the lungs, liver, and pancreas and other glands. Patients with cystic fibrosis have an accumulation of thick, sticky mucus in their lungs, which often leads to respiratory complications, including recurrent bacterial infections. With proper medical care, including regular physical therapy to clear the lungs, antibiotics, pancreatic enzyme supplements, and good nutrition, the average life expectancy of a person with cystic fibrosis is currently 35 to 40 years.

The mutations responsible for cystic fibrosis occur in the gene encoding the cystic fibrosis transmembrane conductance regulator (CFTR) ([Fig. 14.12](#)). The CFTR protein is a chloride channel, which acts as a transporter to pump chloride ions out of the cell. Malfunction of CFTR causes ion imbalances that result in abnormal secretions from the many cell types in which the *CFTR* gene is expressed. Many different mutations can contribute to cystic fibrosis, including a specific mutation known as  $\Delta 508$  (*delta 508*), which is a deletion of three nucleotides that eliminates a phenylalanine normally present at position 508 in the protein. The missing amino acid results in a CFTR protein that does not fold properly and is degraded before reaching the membrane. Researchers have created drugs that stabilize the  $\Delta 508$  mutant protein and improve its function.

FIG. 14.12 Effect of a single amino acid deletion in CFTR, the cystic fibrosis transmembrane conductance regulator.

Small deletions or insertions that are not exact multiples of 3 can cause major changes in amino acid sequence of the corresponding proteins because they do not insert or delete entire codons. The effect of such a mutation can be appreciated by seeing how deletion of a single letter turns a perfectly sensible sentence of three-letter words into gibberish. Consider the sentence:

THE BIG BOY SAW THE CAT EAT THE BUG

If the red **E** is deleted, the new reading frame for three-letter words is as follows:

THB IGB OYS AWT HEC ATE ATT HEB UG

The result is unintelligible. Similarly, an insertion of a single nucleotide causes a one-nucleotide shift in the reading frame of the mRNA, and it changes all codons following the site of insertion. For this reason, such mutations are called **frameshift mutations**. Because frameshift mutations so profoundly alter the amino acid sequence, the mutant protein does not fold properly into its tertiary structure and becomes nonfunctional.

**Fig. 14.13** shows the consequences of a frameshift mutation in the  $\beta$ -globin gene. The normal sequence in **Fig. 14.13a** corresponds to amino acids 5–10. The frameshift mutation in **Fig. 14.13b** is caused by the insertion of a **C—G** base pair. In turn, the mRNA transcript of the DNA also has a single-base insertion. When this mRNA is translated, the one-nucleotide shift in the reading frame results in an amino acid sequence that bears no resemblance to the original protein. All amino acids downstream of the site of insertion are changed, resulting in loss of protein function.

FIG. 14.13 A frameshift mutation. A frameshift mutation changes the translational reading frame.

## Some mutations are due to the insertion of a transposable element.

An important source of new mutations in many organisms is the insertion of movable DNA sequences into or near a gene. Such movable DNA sequences are called **transposable elements** or **transposons**. As we saw in [Chapter 13](#), the genomes of virtually all organisms contain several types of transposable element, each present

in multiple copies per genome.

Transposable elements were discovered by American geneticist Barbara McClintock in the 1940s ([Fig. 14.14](#)). She studied corn (maize) because genetic changes that affect pigment formation can be observed directly in the kernels, which are normally purple. Since McClintock's work, biologists have discovered many different types of transposable elements, most ranging in length from a few hundred to a few thousand base pairs. When such a large piece of DNA inserts into a gene, it can interfere with transcription, cause errors in RNA processing, or disrupt the open reading frame. The result in the case of maize is that the cell is unable to produce pigment, so the kernels will be yellow.

#### HOW DO WE KNOW?

### FIG. 14.14

## What causes sectoring in corn kernels?

#### BACKGROUND

In the late 1940s, Barbara McClintock studied corn (*Zea mays*). Nonmutant corn has purple kernels, resulting from synthesis of purple anthocyanin pigment in every cell of the kernel ([Fig. 14.14a](#)). Mutant cells produce no purple pigment, resulting in yellow kernels. McClintock noticed that, in some mutant corn, speckles or streaks of purple pigment could be seen in many otherwise yellow kernels, and some kernels were entirely purple ([Fig. 14.14b](#)).

SOURCES: a. photo\_journey/Shutterstock;  
b. Robert Martienssen, Cold Spring Harbor Laboratory.

### HYPOTHESIS

McClintock hypothesized that the yellow mutation resulted from insertion of a transposable element, which she called *Dissociation (Ds)*, that had jumped into a site near or in the anthocyanin pigment gene and disrupted its function. She attributed the speckles of purple color in the yellow kernels to cell lineages in which the transposable element had jumped out again, restoring the nonmutant function of the anthocyanin gene.

### EXPERIMENT AND RESULTS

By a series of genetic crosses, McClintock showed that the jumping, or transposition, of *Ds* was due to a different genetic element, which she called *Activator (Ac)*, located on another chromosome. She set up crosses in which she could track the *Ac*-bearing chromosome. She observed that in the presence of *Ac*, cells in mutant yellow kernels could revert to normal purple, resulting in purple speckles in an otherwise yellow kernel. From this observation, she inferred that the *Ds* element had jumped out of the anthocyanin gene in these cells, restoring its function. She also demonstrated that in cells in which the original purple color was restored, there were mutations elsewhere in the genome. From this observation, she inferred that after jumping out of the anthocyanin gene, the *Ds* element had become integrated elsewhere in the genome, where it disrupted the function of a different gene.

### CONCLUSION

McClintock's conclusion is illustrated in [Fig. 14.14c](#): transposable elements can be excised from their original position in the genome and

inserted into another position.

#### FOLLOW-UP WORK

McClintock won the Nobel Prize in Physiology or Medicine in 1983. Later experiments showed that *Ds* is a transposable element that lacks a functional gene for transposase, the enzyme needed for the element to move, and *Ac* is a transposable element that encodes transposase. *Ac* produces active transposase that allows *Ds* to move. Much additional work has shown that many different types of transposable elements exist and that they are ubiquitous among organisms.

#### Self-Assessment Questions

7. What are the effects of nonsynonymous, synonymous, and nonsense mutations on a protein? Are these mutations usually harmful, beneficial, or neutral?
8. What are the effects of small insertions or deletions on a protein? Are these mutations usually harmful, beneficial, or neutral?

9. The coding sequences of genes that specify proteins with the same function in related species sometimes differ from each other by an insertion or deletion of contiguous nucleotides. The number of nucleotides that are inserted or deleted is almost always an exact multiple of 3. Why is this expected?
10. Given the discussion of the human genome in [Chapter 13](#), would you predict that most mutations in humans would be harmful, beneficial, or neutral?

## 14.4 CHROMOSOMAL MUTATIONS

Whereas most mutations involve only one or a few nucleotides, some affect larger regions extending over hundreds of thousands or millions of nucleotides and have effects on chromosome structure that are often large enough to be visible through an ordinary optical microscope.

Chromosomal mutations can delete or duplicate regions of a chromosome containing several or many genes, and the resulting change in gene copy number also changes the amount of the products of these genes in the cell. Chromosomal mutations can also alter the linear order of genes along a chromosome or interchange the arms of nonhomologous chromosomes. While these types of chromosomal mutations do not change gene copy number, they do affect chromosome pairing and segregation in meiosis. These effects distinguish chromosome abnormalities from small-scale mutations.

### Duplications and deletions result in gain or loss of DNA.

Among the most common chromosomal abnormalities are those in which a segment of the chromosome either is present in extra copies or is missing altogether ([Fig. 14.15](#)). A chromosome in which a region is present twice, instead of once, is said to contain a **duplication** ([Fig. 14.15a](#)). Although large duplications that include hundreds or thousands of genes are usually harmful and quickly eliminated from the population, small duplications including only one or a few genes can be maintained over many generations. Usually, duplication of a

region of the genome is less harmful than deletion of the same region.

FIG. 14.15 Duplication and deletion. (a) In a duplication, a segment of chromosome is repeated. (b) In a deletion, a segment of chromosome is missing.

A **deletion** is a region of the chromosome that is missing. An example is shown in [Fig. 14.15b](#). A deletion can result from an error in replication or from the joining of breaks in a chromosome that occur on either side of the deleted region. Even though a deletion may eliminate a gene that is essential for survival, the deletion can persist in the population because chromosomes usually occur in homologous pairs ([Chapter 13](#)). If one member of a homologous pair has a deletion of an essential gene but the gene is present in the other member of the pair, that one copy of the gene is often sufficient for survival and reproduction. In these cases, the deletion can be transmitted from generation to generation, as long as the chromosome with the deletion is present along with a normal chromosome.

Deletions or duplications that include the **centromere**, the site associated with attachment of the spindle fibers that move the chromosome during cell division ([Chapter 11](#)), are rarely observed. An abnormal chromosome without a centromere, or one with two centromeres, is usually lost within a few cell divisions because it

cannot be directed properly into the daughter cells during cell division.

## Gene families arise from gene duplication and divergence.

Small duplications play an important role in the origin of new genes in the course of evolution. In most cases, when a gene is duplicated, one of the copies is free to change without harming the organism because the other copy continues to carry out the normal function of the gene. Occasionally, a mutation in the “extra” copy of the gene may result in a beneficial effect on survival or reproduction, so that gradually a new gene is formed from the duplicate. These new genes usually have a function similar to that of the original gene.

This process of creating new genes from duplicates of old ones is known as **duplication and divergence**. The term “divergence” refers to the slow accumulation of different mutations in duplicate copies of a gene that occurs on an evolutionary time scale. Multiple rounds of duplication and divergence can give rise to a group of genes with related functions known as a **gene family**. The largest gene family in the human genome includes approximately 400 genes and encodes proteins that detect odors. These proteins are structurally very similar, but differ in the region that binds small odor molecules. It is the diversity of the odorant binding sites that allows us to identify so many different smells.

Most gene families are not as large and diverse as that for odor detection. **Fig. 14.16** shows the evolutionary origin of the family of globin genes, which in humans are spread across about 50 kb of

chromosome 11. The globin gene family consists of several genes that are expressed at various times during development (embryo, fetus, or adult). The sequences are all similar enough to imply that the genes arose through duplication and divergence.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 14.16 Origin of the  $\beta$ -globin gene family. The  $\beta$ -globin gene family evolved through several episodes of duplication and divergence. Data from Y. A. Trusov and P. H. Dear, 1996, "A Molecular Clock Based on the Expansion of Gene Families," *Nucleic Acids Research* 24(6):995–999.

## Copy-number variation constitutes a significant proportion of genetic variation.

In the modern human population, a common form of genetic variation among individuals is differences in the number of copies of a region of the genome due to duplication and deletion. These differences are called **copy-number variations (CNVs)**. The regions involved in CNVs are large and may include one or more genes. An example is

shown in [Fig. 14.17](#). The multiple copies of the CNV region are usually located adjacent to one another along the chromosome. Across the genome as a whole, approximately 10% to 15% of the genome is subject to copy-number variation, and the average CNV length is 200 kb to 300 kb.

FIG. 14.17 Copy-number variation in a region of a chromosome.

Some CNVs occur in noncoding regions, but others consist of genes that are present in multiple tandem copies along the chromosome. An example is the human gene *AMY1* for the salivary gland enzyme amylase, which aids in the digestion of starch. This gene is located on chromosome 1, and the *AMY1* copy number differs from one chromosome 1 to the next. [Fig. 14.18](#) shows the distribution of the *AMY1* copy number along chromosome 1 in two groups of people: societies with a long history of a high-starch diet, and societies with a long history of a low-starch diet. There is a clear tendency for chromosomes from the latter group to have fewer copies of *AMY1* than those from the former group. A plausible hypothesis is that extra copies

were selected in groups with a high-starch diet because of the advantage the extra copies conferred in digesting starch.

FIG. 14.18 Copy number variation in a gene that helps break down starch. Copy numbers of *AMY1* vary between societies with high-starch and low-starch diets. Data from G. H. Perry, N. J. Dominy, K. G. Claw, A. S. Lee, H. Fiegler, R. Redon, J. Werner, F. A. Villanea, J. L. Mountain, R. Misra, N. P. Carter, C. Lee, and A. C. Stone, 2007, “Diet and the Evolution of Human Amylase Copy Number Variation,” *Nature Genetics* 39:1256–1260.

## Tandem repeats are useful in DNA typing.

A special type of CNV consists of short sequences (2–50 base pairs) that are repeated in multiple tandem copies, called a **tandem repeat**. At each location, the number of copies of the short sequence may differ from chromosome to chromosome. The human genome contains tens of thousands of locations where one chromosome differs from another in the size of the tandem repeat (the number of copies of the short

sequence). Just as an individual has two copies of each gene, possibly with two different alleles, so each individual has two copies of each of these tandem repeats. Each location with a tandem repeat typically has many alleles differing in copy number, so that, except for identical twins, an individual's genotype at 6–8 different locations is usually sufficient to identify the individual uniquely. Such differences among individuals are the basis of **DNA typing**, in which the analysis of a small quantity of DNA can be as reliable for identifying individuals as fingerprints. As a consequence, DNA typing is often called **DNA fingerprinting**.

Although the number of alleles of a particular tandem repeat at a given location in the genome can be very large in the population as a whole, any one diploid individual can have only 2 alleles inherited one each from the mother and the father. An example with 5 alleles is shown in **Fig. 14.19**, where the repeated sequence (AGT) is shown in green between the flanking unique sequences. With 5 alleles, there are 5 possible homozygous genotypes and 10 possible heterozygous genotypes. The genotypes can be distinguished by DNA sequencing or other methods, but originally they were visualized by separating the resulting molecules by size using gel electrophoresis (**Chapter 12**). The pattern of bands expected from the DNA in each genotype formed from the alleles in **Fig. 14.19a** is shown in **Fig. 14.19b**. Notice that each genotype yields a distinct pattern of bands, so these patterns can be used to identify the genotype of any individual for a particular region of DNA.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 14.19 Tandem repeats in DNA typing. (a) The number of short, repeated sequences at a given site in a human chromosome can vary. (b) These differences can be visualized using polymerase chain reaction (PCR) amplification followed by gel electrophoresis.

The lane labeled “E” at the far right in [Fig. 14.19b](#) shows the DNA bands for this same polymorphism from biological material collected at the scene of a crime. In this case, the bands in lane E imply that the source of the evidence is an individual of genotype  $A_2/A_4$  because this is the only genotype with bands with vertical positions in the gel that exactly match those of the evidence sample. A single polymorphism of the type shown in [Fig. 14.19](#) is not enough to say for sure that two pieces of DNA come from the same person, but because tandem repeat sites are scattered throughout the human genome, many multiple-allele tandem repeats can be examined. If six or eight of these polymorphisms match between two samples, it is very likely that the samples come from the same individual (or from identical twins). On

the other hand, if any of the polymorphisms fails to match band for band, then it is almost certain that the samples come from different individuals (barring technical mishaps that lead to contaminated, degraded, or mislabeled DNA).

One of the advantages of DNA typing is that only a small amount of DNA is needed. Even minuscule amounts of DNA can be typed, so tiny spots of blood, semen, or saliva are sufficient samples. A cotton swab wiped across the inside of your cheek will contain enough DNA for typing; so will a discarded paper cup or a cigarette butt.

## An inversion has a chromosomal region reversed in orientation.

Chromosomes in which the normal order of a block of genes is reversed contain an **inversion** ([Fig. 14.20](#)). An inversion is typically produced when the region between two breaks in a chromosome is flipped in orientation before the breaks are repaired. Especially in large genomes, the breaks are likely to occur in noncoding DNA rather than within a gene. Whereas large inversions can cause problems in meiosis, small inversions are common in many populations and play an important role in chromosome evolution. A small inversion may have almost no effect on the organism because it still contains all of the genes present in the original chromosome, merely flipped in their order, and is too small to cause problems in meiosis. The accumulation of inversions over evolutionary time explains in part why the order of genes along a chromosome can differ even among closely related species.

## A reciprocal translocation joins segments from nonhomologous chromosomes.

A **reciprocal translocation** ([Fig. 14.21](#)) occurs when two different (nonhomologous) chromosomes undergo an exchange of parts. In the formation of a reciprocal translocation, both chromosomes are broken and the terminal segments are exchanged before the breaks are repaired. In large genomes, the breaks are likely to occur in noncoding DNA, so the breaks themselves do not usually disrupt gene function.

Because reciprocal translocations change only the arrangement of

genes and not their number, most reciprocal translocations do not affect the survival of organisms. Proper gene dosage requires the presence of both parts of the reciprocal translocation, however, as well as one copy of each of the normal homologous chromosomes.

Problems can arise in meiosis because both chromosomes involved in the reciprocal translocation may not move together into the same daughter cells, resulting in gametes with only one part of the reciprocal translocation. This inequality does upset gene dosage, because these gametes have extra copies of genes in one of the chromosomes and are missing copies of genes in the other.

#### Self-Assessment Questions

11. Which type of chromosomal abnormality—deletion, duplication, inversion, or translocation—would you expect to have the greatest effect on the organisms that carry it, and why?
12. How do gene families, such as the odorant receptor gene family, arise in evolution?

# 14.5 DNA DAMAGE AND REPAIR

Mutations result from unrepaired errors in DNA replication or from damage to DNA that is not repaired. DNA is a fragile molecule, prone to damage of many different kinds. Every day, in each cell in our bodies, the DNA is damaged in some way at tens of thousands of places along the molecule. Fortunately, cells have evolved mechanisms for repairing various types of damage and restoring the DNA to its original condition, which helps explain the low mutation rate in most organisms. The importance of DNA repair was recognized by the 2015 Nobel Prize in Chemistry awarded to Tomas Lindahl, Paul Modrich, and Aziz Sancar for their discoveries of key repair mechanisms. In this section, we examine some of the major types of DNA damage and some of the ways in which it is repaired.

## DNA damage can affect both DNA backbone and bases.

Most mutations, whether small-scale or chromosomal, are spontaneous and occur naturally. However, mutations can also be induced by radiation or chemicals. [Mutagens](#) are agents that increase the probability of mutation. The presence of a mutagen can increase the probability of mutation by a factor of 100 or more.

Some of the most frequent types of DNA damage induced by mutagens are illustrated in [Fig. 14.22](#), which shows a highly mutated DNA molecule. Some types of damage affect the structure of the DNA double helix. These include breaks in the sugar–phosphate backbone,

one of the main mutagenic effects of X-rays. Breaks can occur in just one or both strands of a DNA molecule and can result in the types of chromosomal mutations described earlier. Ultraviolet light can cause cross-links between adjacent pyrimidine bases, especially thymine, resulting in the formation of thymine dimers that warp the backbone.

Yet another type of structural damage is loss of a base from one of the deoxyribose sugars, resulting in a gap in one strand where no base is present. Spontaneous loss of a purine base is one of the most common types of DNA damage, occurring at the rate of approximately 13,000 purines lost per human cell per day. Most of these mutations result from the interaction between DNA and normal metabolic by-products. The mutation rate increases with age, and it can also be increased by exposure to oxidizing agents such as household bleach or hydrogen peroxide.

Other types of damage alter the chemical structure of the bases themselves, making them prone to mispairing. Chemicals that are highly reactive also tend to be mutagenic, often because they add bulky side groups to the bases that hinder proper base pairing. The main

environmental source of such chemicals is tobacco smoke. Other chemicals can perturb the DNA replication complex and cause the insertion or deletion of one or occasionally several nucleotides.

## Most DNA damage is corrected by specialized repair enzymes.

Cells contain many specialized DNA-repair enzymes that correct specific kinds of damage, and in this section we examine a few examples. Perhaps the simplest is the repair of breaks in the sugar–phosphate backbone, which are sealed by [DNA ligase](#), an enzyme that can repair the break by using the energy in ATP to join the 3' hydroxyl group of one end to the 5' phosphate group of the other end. Most organisms have multiple different types of DNA ligase. One type of ligase seals single-stranded breaks in DNA, and a different type seals double-stranded breaks. Double-stranded breaks are less likely to be repaired than single-stranded breaks, in many cases resulting in chromosomal rearrangements. In addition to their role in DNA replication and repair, ligases are an important tool in research in molecular biology because they allow DNA molecules from different sources to be joined to produce recombinant DNA ([Chapter 12](#)).

As we saw earlier in this chapter, mispairing of bases during DNA replication leads to the incorporation of incorrect nucleotides that can become nucleotide substitutions in the next round of replication if they are not corrected. Approximately 99% of the mispaired bases are corrected immediately by the proofreading function of DNA polymerase, in which the mispaired nucleotide is removed immediately after incorporation and replaced by the correct nucleotide ([Chapter 12](#)).

Even after proofreading by DNA polymerase, the proportion of mismatched nucleotides in newly replicated DNA is about  $10^{-6}$ , which is at least 1000 times greater than the actual frequency of errors in cellular organisms (see [Fig. 14.5a](#)). What accounts for the difference is a second-chance mechanism for catching mismatches that is known as **mismatch repair** ([Fig. 14.23](#)).

FIG. 14.23 Mismatch repair. In mismatch repair, the segment of a DNA strand containing the mismatch is removed and then resynthesized.

In the bacterium *E. coli*, mismatch repair begins when a protein known as MutS recognizes and binds to the site of a mismatch ([Fig. 14.23a](#)) and brings two other proteins (MutL and MutH) to the site. MutL determines which DNA backbone will be cleaved, and MutH cleaves the backbone in the vicinity of the mismatch ([Fig. 14.23b](#)). An exonuclease degrades the cleaved strand to a distance beyond the site of the mismatch ([Fig. 14.23c](#)). A DNA polymerase then synthesizes new DNA to fill the gap, correcting the mismatch, and a DNA ligase seals the remaining nick in the DNA backbone ([Fig. 14.23d](#)). Mismatch repair usually, but not always, cleaves the daughter strand, so the corrected strand matches the parental template strand.

Eukaryotes have proteins corresponding to those in [Fig. 14.23](#). The importance of mismatch repair in these organisms is underlined by the finding that a genetic predisposition to certain types of colon cancer results from mutations in the human counterparts of the *MutS* and *MutL* genes.

The result of proofreading by DNA polymerase and mismatch repair is increased fidelity of DNA replication. Cells have evolved many other systems that repair different types of DNA damage that can occur, even in nondividing cells such as those in the adult brain, heart, liver, and kidney. One example is [base excision repair](#), which corrects abnormal or damaged bases. In the first step of base excision repair, an abnormal or damaged base is cleaved from the sugar in the DNA backbone. Then, the baseless sugar is removed from the backbone, leaving a gap of one nucleotide. Finally, a repair polymerase inserts the correct nucleotide into the gap ([Fig. 14.24](#)).

FIG. 14.24 Base excision repair. In base excision repair, an improper base in DNA and its deoxyribose sugar are both removed, and the resulting gap is then repaired.

Cells have also evolved mechanisms to repair short stretches of DNA containing mismatched or damaged bases. One of these is known as **nucleotide excision repair**, which has a similar mechanism of action to mismatch repair but uses different enzymes (**Fig. 14.25**). Instead of degrading a DNA strand in a nucleotide by nucleotide fashion until the mismatch is removed, nucleotide excision repair

removes an entire damaged section of a strand at once. Nucleotide excision repair is also used to remove nucleotides with bulky side groups, as well as thymine dimers resulting from ultraviolet light.

FIG. 14.25 Nucleotide excision repair. In nucleotide excision repair, a damaged segment of a DNA strand is removed and resynthesized using the undamaged partner strand as a template.

The importance of nucleotide excision repair is illustrated by the disease xeroderma pigmentosum (XP), in which nucleotide excision

repair is defective. People with XP are exquisitely sensitive to the UV radiation in sunlight. Because of the defect in nucleotide excision repair, damage to DNA resulting from UV light is not corrected, leading to the accumulation of mutations in skin cells. The result is high rates of skin cancer. People with XP must minimize their exposure to sunlight and in extreme cases stay out of the sun altogether.

When DNA repair mechanisms function properly, they reduce the rate of mutation to a level that is compatible with life. But they are not perfect, and they do not catch all the mistakes. The result is genetic variation, the raw material of evolution.

#### Self-Assessment Questions

13. Earlier, we described the Lederbergs' experiment, which demonstrated that mutations are not directed by the environment. But mutagens, which are environmental factors, can lead to mutations. What's the difference?
14. What is a mutagen? Name two common mutagens and their effects on DNA.
15. What's the difference between nucleotide excision repair and mismatch repair?

## CORE CONCEPTS SUMMARY

**14.1 GENOTYPE AND PHENOTYPE:** The genetic makeup of a cell or organism is its genotype, and an observable characteristic is its phenotype.

Polymorphisms result from mutations that persist through time and become common in the population. [page 302](#)

The genotype of an organism is its genetic makeup. [page 302](#)

The phenotype of an organism is any observable characteristic of that organism, such as its appearance, physiology, or behavior. The phenotype results from a complex interplay of the genotype and the environment. [page 302](#)

Different forms (sequences) of genes are called alleles. [page 302](#)

A person's genotype can be homozygous, with two alleles of the same type (one from each parent), or heterozygous, with a different type of allele from each parent. [page 302](#)

Mutations can be neutral (no effect on survival or reproduction), harmful (associated with decreased survival or reproduction), or beneficial (associated with increased survival or reproduction). [page 302](#)

**14.2 THE NATURE OF MUTATIONS:** Mutations are very rare for any given nucleotide and occur randomly without regard to the needs of an organism.

For an individual nucleotide, the frequency of mutation is very rare,

though it differs among species. [page 305](#)

Mutations are common across an entire genome and across many cell divisions. [page 305](#)

Germ-line mutations occur in haploid gametes as well as in the diploid cells that give rise to them, whereas somatic mutations occur in nonreproductive cells. Only mutations in germ cells are transmitted to progeny and play a role in genetic variation and evolution. [page 306](#)

Mutations are random, in that they occur without regard to the needs of an organism. This principle can be demonstrated by replica plating of bacterial colonies in the absence and presence of an antibiotic. [page 308](#)

**14.3 SMALL-SCALE MUTATIONS:** Small-scale mutations include point mutations, insertions and deletions, and movement of transposable elements.

A point mutation, or nucleotide substitution, is a change of one base for another. [page 310](#)

A single-nucleotide polymorphism (SNP) is a difference in a single nucleotide. [page 310](#)

The effect of a point mutation depends on where it occurs. If it arises in noncoding DNA, it will likely have little or no effect on an organism. If it arises in a protein-coding gene, it can result in a change in the amino acid sequence (nonsynonymous mutation), no change in the amino acid sequence (synonymous mutation), or the

introduction of a stop codon (nonsense mutation). [page 310](#)

Small insertions (or deletions) in DNA add (or remove) one base or a few contiguous bases. Their effect depends on where in the genome they occur and on their size. An insertion or deletion of a single nucleotide in a protein-coding gene results in a frameshift mutation, in which all the codons downstream of the insertion or deletion are changed. [page 311](#)

Transposable elements are DNA sequences that can jump from one place in a genome to another. They can affect the expression of a gene if they are inserted into or near a gene. [page 312](#)

**14.4 CHROMOSOMAL MUTATIONS:** Chromosomal mutations involve large regions of one or more chromosomes.

A duplication is a region of the chromosome that is present two times, whereas a deletion is the loss of part of a chromosome. [page 314](#)

Duplications and deletions both affect gene dosage, which can have important effects on a cell or organism. [page 314](#)

Gene duplication followed by evolutionary divergence results in gene families made up of genes with related, but not identical, functions. [page 314](#)

Copy-number variation (CNV) is a difference in the number of copies of a particular DNA sequence among chromosomes. [page 314](#)

DNA typing (DNA fingerprinting) analyzes genetic polymorphisms

at multiple genes with multiple alleles, such as tandem repeat polymorphisms. Because there are so many possible genotypes in the population, this technique can uniquely identify an individual with high probability. [page 316](#)

An inversion is a segment of a chromosome in reverse orientation. [page 316](#)

A reciprocal translocation involves the exchange of a part of one chromosome with another. Reciprocal translocations do not affect gene dosage, but can lead to problems during meiosis. [page 317](#)

**14.5 DNA DAMAGE AND REPAIR:** Mutations can occur spontaneously or be induced by mutagens, but most DNA damage is repaired.

Some types of damage alter the structure of DNA, such as single-stranded and double-stranded breaks, cross-linked thymine dimers, and missing bases. [page 317](#)

Other types of DNA damage, such as changes in the side groups that form hydrogen bonds and the addition of side groups that interfere with base pairing, affect the bases themselves. [page 318](#)

DNA ligase seals breaks in DNA; thus, it is an important tool for molecular biologists. [page 318](#)

Mismatch repair provides a backup mechanism for mistakes not caught by the proofreading function of DNA polymerase. [page 318](#)

Base excision repair corrects individual nucleotides and involves several DNA repair enzymes working together. [page 319](#)

Nucleotide excision repair functions similarly to mismatch repair but excises longer stretches of damaged nucleotides. [page 319](#)

## CHAPTER 15 Mendelian Inheritance

Edoma/Getty Images

---

### CORE CONCEPTS

**15.1 EARLY THEORIES OF INHERITANCE:** Early theories of heredity incorrectly assumed the inheritance of acquired characteristics and blending of parental traits in the offspring.

## **15.2 FOUNDATIONS OF MODERN TRANSMISSION GENETICS:**

The study of modern transmission genetics began with Gregor Mendel, who used the garden pea and studied traits with contrasting characteristics.

**15.3 SEGREGATION:** Mendel's first key discovery was the principle of segregation, which states that members of a gene pair separate equally into gametes.

**15.4 INDEPENDENT ASSORTMENT:** Mendel's second key discovery was the principle of independent assortment, which states that different gene pairs segregate independently of one another.

**15.5 HUMAN GENETICS:** The patterns of inheritance that Mendel observed in peas can also be seen in humans.

---

Except for identical twins, each of us has his or her own personal genome, a unique human genome differing from all that have existed before and from all that will come after. Genetic variation from one person to the next leads in part to our individuality, from differences in appearance to differences in the ways our bodies work. Examples of genetic variation in the human population range from harmless curiosities, such as the genetic difference in taste receptors that determines whether you taste broccoli as being unpleasantly bitter, to mutant forms of genes resulting in serious diseases such as sickle-cell anemia or emphysema.

This chapter focuses on how that genetic variation is inherited. Transmission genetics deals with the manner in which genetic differences among individuals are passed from generation to generation. We are all aware of genetics. We know that children

resemble their parents and that there are sometimes uncanny similarities among even distant relatives. Some patterns, however, are more difficult to discern. Traits such as eye color, nose shape, or risk for a particular disease may be passed down faithfully generation after generation, but sometimes they are not, and sometimes they appear and disappear in seemingly random ways.

As a modern science, transmission genetics began with the pea-breeding experiments carried out by the monk Gregor Mendel in the 1860s. However, even before then, people understood enough about inheritance that they were able to select crops and livestock with particular characteristics.

# 15.1 EARLY THEORIES OF INHERITANCE

Thousands of years before Mendel, many societies carried out practical plant and animal breeding. The ancient practices were based on experience rather than on a full understanding of the rules of genetic transmission, but they were nevertheless highly successful. In Mesoamerica, for example, Native Americans chose corn (maize) plants for cultivation that had the biggest ears and softest kernels. Over many generations, their cultivated corn came to have increasingly less physical resemblance to its wild ancestral species. Similarly, people in the Eurasian steppes selected their horses for a docile temperament suitable for riding or for hitching to carts or sleds. Practical breeding of this kind provided the crops and livestock from which most of our modern domesticated animals and plants derive.

## Early theories of heredity predicted the transmission of acquired characteristics.

The first written speculations about mechanisms of heredity were made by the ancient Greeks. Hippocrates (460–377 BCE), considered the founder of Western medicine, proposed that each part of the body in a sexually mature adult produces a substance that collects in the reproductive organs and that determines the inherited characteristics of the offspring. An implication of this theory is that any [trait](#), or characteristic, of an individual can be transmitted from parent to offspring. Even traits that are acquired during the lifetime of an

individual, such as muscle strength or bodily injury, were thought to be heritable because of the substance supposedly passed from each body part to the reproductive organs. The related term “phenotype” ([Chapter 14](#)) refers to the particular manifestation of a trait in an individual.

The theory that acquired characteristics can be inherited was invoked to explain such traits as the webbed feet of ducks, which were thought to result from many successive generations in which adult ducks stretched the skin between their toes while swimming and then passed this trait to their offspring. A few decades after Hippocrates, however, Aristotle (384–322 BCE) emphasized several observations that the theory of inheritance of acquired characteristics cannot account for:

- Traits such as hair color can be inherited, but it is difficult to see how hair—a nonliving tissue—could send substances to the reproductive organs.
- Traits that are not yet present in an individual can be transmitted to the offspring. For example, a father and his adult son can both be bald, even if the son was born before the father became bald.
- Parts of the body that are lost as a result of surgery or accident are not missing in the offspring.

From these and other observations, Aristotle concluded that the process of heredity transmits only the potential for producing traits present in the parents, and not the traits themselves. Nevertheless, Hippocrates’ theory influenced biology until well into the 1800s. It was incorporated into an early theory of evolution proposed by the French

biologist Jean-Baptiste Lamarck around 1800. Later, Charles Darwin developed an alternative theory of evolution: the theory of evolution by natural selection ([Chapter 20](#)).

While traits acquired during the lifetime of a parent are not transmitted to the offspring, parental misfortune or misbehavior can nevertheless result in impaired fetal development and in some cases permanent damage. For example, maternal malnutrition, drug addiction, alcoholism, infectious disease, and other conditions can severely affect the fetus, but these effects are due to disruption of fetal development and not to changes in the genome.

## Belief in blending inheritance discouraged studies of hereditary transmission.

Darwin subscribed to the now-discredited model of [blending inheritance](#), in which traits in the offspring resemble the average of those in the parents. For example, this model predicts that the offspring of plants with blue flowers and those with red flowers will have purple flowers. While traits of offspring are sometimes the average of those of the parents (think of certain cases of human height), the idea of blending inheritance—which implies the blending of the genetic material—as a general rule presents problems. For example, it cannot explain the reappearance of a trait several generations after it apparently “disappeared” in a family, such as red hair or blue eyes.

Another difficulty with the concept of blending inheritance is that

variation is lost over time. Consider an example where black rabbits are rare and white rabbits are common ([Fig. 15.1](#)). Black rabbits, being rare, are most likely to mate with the much more common white rabbits. If blending inheritance occurs, the result will be gray rabbits. These will also mate with white rabbits, producing lighter-gray rabbits. Over time, the population will end up being all white, or very close to white, and there will be less variation. The only way that black rabbits will be present is if they are reintroduced into the population through mutation or migration.

FIG. 15.1 Blending inheritance. This now-discredited model predicts loss of variation over time and blending of genetic material, which is not observed.

Whatever the trait may be, blending inheritance predicts that inheritance will tend to be a homogenizing force, producing in each generation a blend of the original phenotypes. Of course, we know from common experience that variations in most populations are plentiful.

It is ironic that Darwin believed in blending inheritance because this mechanism of inheritance is incompatible with his theory of evolution by means of natural selection. The incompatibility was pointed out by some of Darwin's contemporaries, and Darwin himself recognized it as a serious problem. The problem with blending inheritance is that rare variants, such as the black rabbits in the previously mentioned example, will have no opportunity to increase in frequency because in each generation they must (most likely) mate with one of the superabundant white rabbits.

Although Darwin was convinced that he was right about natural selection, he was never able to reconcile his theory with the concept of blending inheritance. Unbeknownst to him, the solution had already been discovered in experiments carried out by Gregor Mendel (1822–1884), an Augustinian monk in a monastery in the city of Brno in what is now the Czech Republic. Mendel's key discovery was this: traits are not transmitted in inheritance, but rather genes are transmitted.

#### Self-Assessment Question

1. What are two observations that argue against the idea of blending inheritance?

## 15.2 FOUNDATIONS OF MODERN TRANSMISSION GENETICS

Mendel's scientific fame rests on the pea-breeding experiments that he carried out in the years 1856 to 1864 ([Fig. 15.2](#)), in which he demonstrated the basic principles of transmission genetics. As we will see in [Chapter 17](#), most genetic variation in populations is due to multiple genes interacting with one another and with the environment, while traits due to single genes, such as those that Mendel studied, tend to be rare. Nevertheless, Mendel's experiments were so simple and presented with such clarity that they still serve as examples of the scientific method at its best ([Chapter 1](#)).

Sources: Juliette Wade/Getty Images; Authenticated News/Getty Images.

FIG. 15.2 Gregor Mendel and his experimental organism, the pea plant.

Mendel's experimental organism was the garden pea.

For his experimental material, Mendel used several strains of ordinary garden peas (*Pisum sativum*) that he obtained from local seed suppliers. His experimental approach was similar to that of a few botanists of the eighteenth and nineteenth centuries who studied the results of **hybridization**, or interbreeding between two different varieties or species of an organism. Where Mendel differed from his predecessors was in paying close attention to a small number of easily classified traits with contrasting characteristics. For example, where one variety, or strain, of peas had yellow seeds, another had green seeds; and where one had round seeds, another had wrinkled seeds (**Fig. 15.3**). Altogether Mendel studied seven physical features expressed in contrasting fashion among the strains: seed color, seed shape, pod color, pod shape, flower color, flower position, and plant height.

The expression of each trait in each of the original strains that Mendel obtained was **true breeding**, which means that the physical appearance of the offspring in each successive generation is identical to the previous one. For example, plants of the strain with yellow seeds produced only yellow seeds, and those of the strain with green seeds produced only green seeds. Likewise, plants of the strain with round seeds produced only round seeds, and those of the strain with wrinkled seeds produced only wrinkled seeds.

The objective of Mendel's experiments was simple. By means of crosses between the true-breeding strains and crosses among their progeny, Mendel hoped to determine whether statistical patterns could be seen in the occurrence of the contrasting characteristics, such as yellow seeds or green seeds. If such patterns could be found, he would seek to devise a hypothesis to explain them and then use his hypothesis to predict the outcome of further crosses.

In designing his experiments, Mendel departed from other plant hybridizers of the time in three important ways:

1. Mendel studied true-breeding strains, unlike many other plant hybridizers, who used complex and poorly defined material.
2. Mendel focused on one trait, or a small number of traits, at a time, with characteristics that were easily contrasted among the true-breeding strains. Other plant hybridizers crossed strains differing in many traits and tried to follow all the traits at once. This resulted in amazingly complex inheritance, and no underlying patterns could be discerned.

3. Mendel counted the progeny of his crosses, looking for statistical patterns in the offspring of his crosses. Others typically noted only whether offspring with a particular characteristic were present or absent, but did not keep track of and count all the progeny of a particular cross.

## In crosses, one of the traits was dominant in the offspring.

Mendel began his studies with crosses between true-breeding strains that differed in a single contrasting characteristic. Crossing peas is not as easy as it may sound. Pea flowers include both female and male reproductive organs enclosed together within petals ([Fig. 15.4](#)).

Because of this arrangement, pea plants usually fertilize themselves (self-fertilize). Performing crosses between different plants is a tedious and painstaking process. First, the flower of the designated female parent must be opened at an early stage and the immature anthers (male reproductive organs) clipped off and discarded, so the plant cannot self-fertilize. Then mature pollen from the designated male parent must be collected and deposited on the stigma (female reproductive organ) of the female parent, from where it travels to the reproductive cells in the ovule at the base of the flower. Finally, a cloth bag must be tied around the female flower to prevent stray pollen from entering. After a few days, a pea pod forms from the fertilized flower, with each ovule having developed into one pea in the pod. No wonder Mendel complained that his eyes hurt!

FIG. 15.4 Crossing pea plants. Crossing plants in a way that isolates either the ovules or the pollen controls which genetic material each parent contributes to the offspring.

For each of the seven pairs of contrasting traits, true-breeding strains differing in the trait were crossed. [Fig. 15.5](#) illustrates a typical result, in this case for a cross between a plant producing yellow seeds and a plant producing green seeds. In these kinds of crosses, the parental generation is referred to as the **P<sub>1</sub> generation**, and the first offspring, or filial, generation is referred to as the **F<sub>1</sub> generation**. In the cross of P<sub>1</sub> yellow × P<sub>1</sub> green, Mendel observed that all the F<sub>1</sub> progeny had yellow seeds. This result was shown to be independent of the seed color of the pollen donor (the male parent) because both of the crosses shown below yielded progeny plants with yellow seeds:

|                                         |   |                                         |   |                           |
|-----------------------------------------|---|-----------------------------------------|---|---------------------------|
| Pollen from strain<br>with yellow seeds | × | Ovules from strain<br>with green seeds  | → | Offspring<br>seeds yellow |
| Pollen from strain<br>with green seeds  | × | Ovules from strain<br>with yellow seeds | → | Offspring<br>seeds yellow |

Crosses like these, in which the expressions of the trait in the female and male parents are interchanged, are known as **reciprocal crosses**. Mendel showed that reciprocal crosses yielded the same result for each of his seven pairs of contrasting traits.

FIG. 15.5 The first-generation hybrid (**F<sub>1</sub>**). A cross between two of Mendel's true-breeding plants (the parental, or **P<sub>1</sub>**, generation) yielded first-generation

hybrids displaying the dominant trait.

Moreover, for each pair of contrasting traits, only one of the traits appeared in the  $F_1$  generation. For simple crosses involving two parents that are true breeding for different traits, the trait that appears in the  $F_1$  generation is said to be **dominant**, and the contrasting trait that does not appear is said to be **recessive**. For each pair of traits illustrated in [Fig. 15.3](#), the dominant trait is shown on the left, and the recessive trait on the right. Thus, yellow seed is dominant to green seed, round seed is dominant to wrinkled seed, and so forth.

Mendel explained these findings by supposing that there is a hereditary factor for yellow seeds and a different hereditary factor for green seeds; likewise, there is a hereditary factor for round seeds and a different one for wrinkled seeds; and so on. We now know that the hereditary factors that result in contrasting traits are different forms of a gene that affect the trait, called **alleles**. The alleles of a gene are variations of the DNA sequence of a gene that occupies a particular region along a chromosome. The particular combination of alleles present in an individual constitutes its **genotype**, and the expression of the trait in the individual constitutes its **phenotype** ([Chapter 14](#)). As noted, Mendel found that, for each of his traits, one phenotype was dominant and the other phenotype was recessive.

In the cross between true-breeding plants that produce yellow seeds and true-breeding plants that produce green seeds, the genotype of each  $F_1$  seed that grows from a female parent flower includes an allele for yellow from the yellow parent and an allele for green from the green

parent. The phenotype of each  $F_1$  seed is nevertheless yellow, because yellow is dominant to green.

The molecular basis of dominance in this case is the fact that, in diploid organisms, only one copy of a gene is needed to carry out its normal function. The yellow color in pea seeds results from an enzyme that breaks down green chlorophyll, allowing yellow pigments to show through. Green seeds result from a mutation in this gene that inactivates the enzyme, so that the green chlorophyll is retained. In an  $F_1$  hybrid, such as that in [Fig. 15.5](#), which receives a nonmutant gene from one parent and a mutant gene from the other, the seeds are yellow because one copy of the nonmutant gene produces enough of the enzyme to break down the chlorophyll to yield a yellow seed.

#### Self-Assessment Questions

2. In his famous paper, Mendel writes that he set out to “determine the number of different forms in which hybrid progeny appear” and to “ascertain their numerical interrelationships.” How did his approach differ from earlier investigations in heredity?
3. What are the differences among gene, allele, genotype, and phenotype?

## 15.3 SEGREGATION

Mendel's most important discovery was that the  $F_1$  progeny of a cross between plants with different traits did not breed true. In the  $F_2$  **generation**, produced by allowing the  $F_1$  flowers to undergo self-fertilization, the recessive trait reappeared (**Fig. 15.6**). Not only did the recessive trait reappear, it reappeared in a definite numerical proportion. Among a large number of  $F_2$  progeny, Mendel found that the dominant : recessive ratio was very close to 3 : 1. The results he observed among the  $F_2$  progeny for each of the seven pairs of traits are given in **Table 15.1**. Across experiments for all seven traits, the ratio of dominant : recessive  $F_2$  offspring was 14,949 : 5010. Although there is variation from one experiment to the next, the overall ratio of 14,949 : 5010 equals 2.98 : 1, which is a very close approximation to 3 : 1.

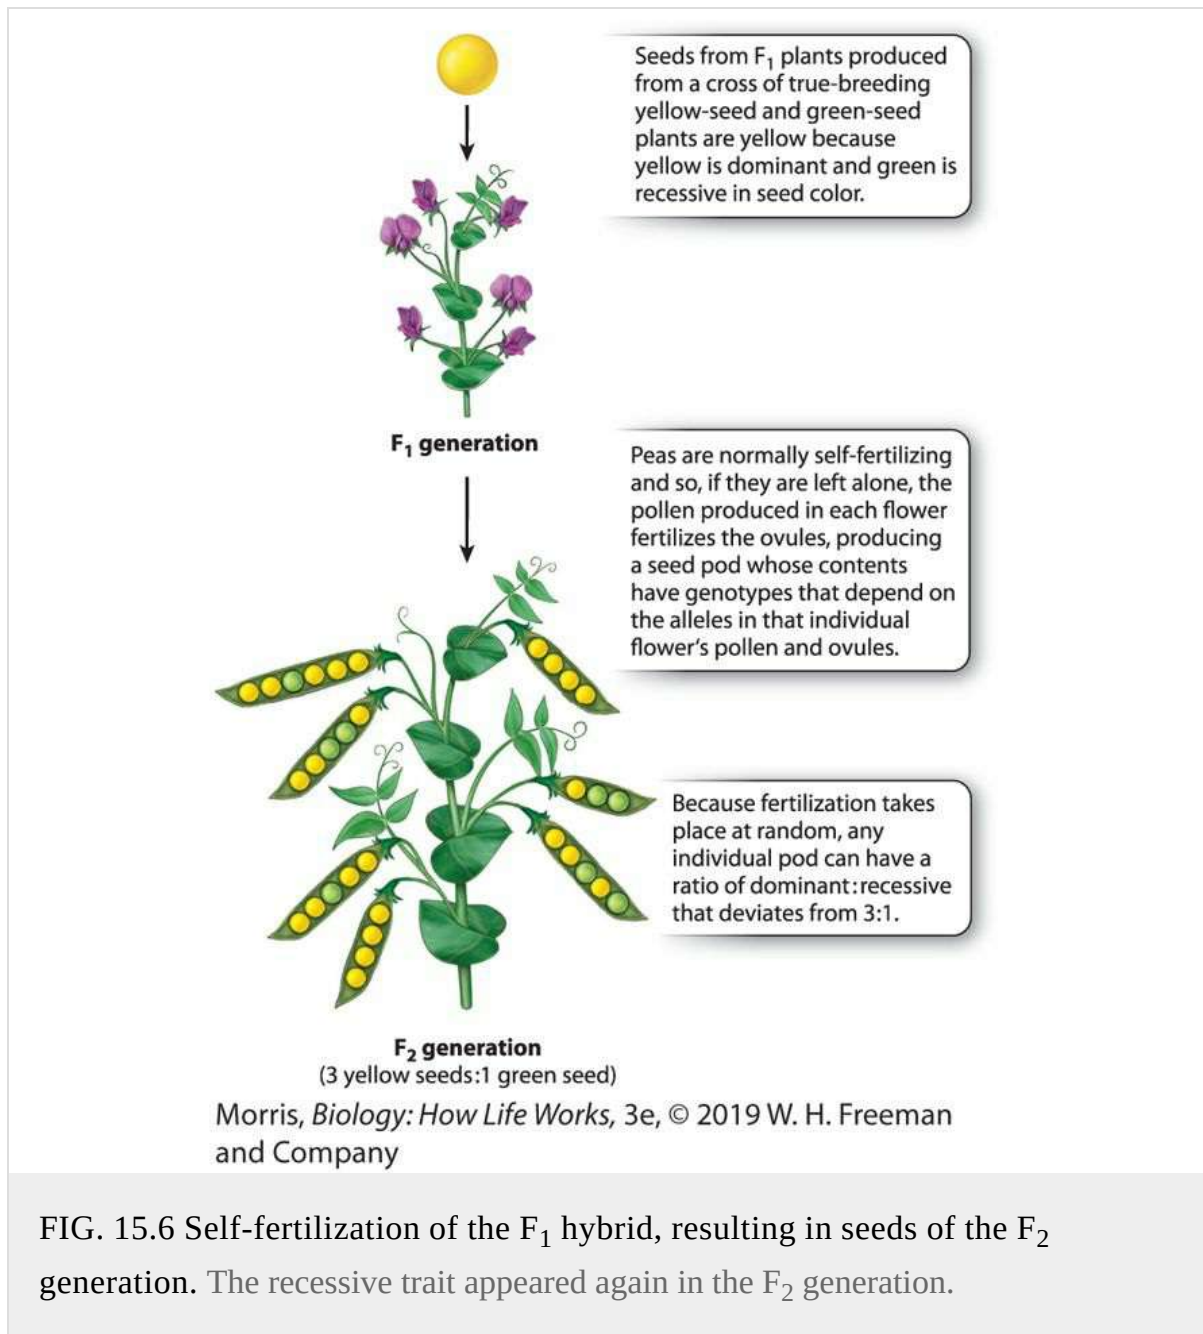

TABLE 15.1 Observed  $F_2$  Ratios in Mendel's Experiments

| TRAIT      | DOMINANT TRAIT | RECESSIVE TRAIT | RATIO    |
|------------|----------------|-----------------|----------|
| Seed color | 6,022          | 2,001           | 3.01 : 1 |
| Seed shape | 5,474          | 1,850           | 2.96 : 1 |
| Pod color  | 428            | 152             | 2.82 : 1 |
| Pod shape  | 882            | 299             | 2.95 : 1 |

|                 |     |     |          |
|-----------------|-----|-----|----------|
| Flower color    | 705 | 224 | 3.15 : 1 |
| Flower position | 651 | 207 | 3.14 : 1 |
| Plant height    | 787 | 277 | 2.84 : 1 |

## Genes come in pairs that segregate in the formation of reproductive cells.

The explanation for the 3 : 1 ratio in the  $F_2$  and Mendel's observations in general can be summarized with reference to [Fig. 15.7](#):

1. Except for cells involved in reproduction, each cell of a pea plant contains two alleles of each gene. In each true-breeding strain constituting the  $P_1$  generation, the two alleles are identical. In [Fig. 15.7](#), we designate the allele associated with yellow seeds as  $A$  and that associated with green seeds as  $a$ . The genotype of the true-breeding strain with yellow seeds can therefore be written as  $AA$ , and that of the true-breeding strain with green seeds as  $aa$ . The  $AA$  and  $aa$  genotypes are said to be [homozygous](#), which means that both alleles inherited from the parents are the same.
2. Each reproductive cell, or [gamete](#), contains only one allele of each gene. In this case, a gamete can contain the  $A$  allele or the  $a$  allele, but not both.
3. In the formation of gametes, the two members of a gene pair [segregate](#) (or separate) equally into gametes, so that half the gametes get one allele and half get the other allele. This separation of alleles into different gametes defines the [principle of segregation](#). In the case of homozygous plants (such as  $AA$  or  $aa$ ), all the gametes from an individual are the same. That is, the

homozygous  $AA$  strain with yellow seeds produces gametes containing the  $A$  allele, and the homozygous  $aa$  strain with green seeds produces gametes containing the  $a$  allele.

4. The fertilized egg cell, called the **zygote**, is formed from the random union of two gametes, one from each parent. For the cross  $AA \times aa$ , the zygote is an  $F_1$  hybrid formed from the union of an  $A$ -bearing gamete with an  $a$ -bearing gamete. Each  $F_1$  hybrid therefore has the genotype  $Aa$  ([Fig. 15.7](#)). The  $Aa$  genotype is **heterozygous**, which means that the two alleles for a given gene inherited from each parent are different. The seeds produced by the  $F_1$  progeny are yellow because yellow is dominant to green. Note that each  $F_1$  progeny contains an  $a$  allele because its genotype is  $Aa$ , but the phenotype of the seed is yellow and indistinguishable from that of an  $AA$  genotype.
5. When the  $F_1$  progeny (genotype  $Aa$ ) form gametes, by the principle of segregation the  $A$  and  $a$  alleles again separate equally so that half the gametes contain only the  $A$  allele and the other half contain only the  $a$  allele ([Fig. 15.7](#)).
6. In the formation of the  $F_2$  generation, the gametes from the  $F_1$  parents again combine at random. The consequences of the random union of gametes can be worked out by means of a checkerboard of the sort shown at the bottom of [Fig. 15.7](#). In this kind of square, which is known as a **Punnett square** after its inventor, the British geneticist Reginald Punnett, the gametes from each parent, each with its respective frequency, are arranged along the top and sides of a grid. Each box in the grid represents the union of the gametes in the corresponding row and column, showing all the possible genotypes of offspring that can result

from random fertilization.

7. The boxes of the Punnett square correspond to all of the possible offspring genotypes of the  $F_2$  generation, with each possible genotype's frequency obtained by multiplying the gametic frequencies in the corresponding row and column. For the example illustrated in [Fig. 15.7](#), the expected genotypes of the offspring are  $\frac{1}{4}$   $AA$ ,  $\frac{1}{2}$   $Aa$ , and  $\frac{1}{4}$   $aa$  (or 1 : 2 : 1). When there is dominance, however, as there is in this case, the  $AA$  and  $Aa$  genotypes have the same phenotype, so the ratio of dominant : recessive phenotypes is 3 : 1. The Punnett square in [Fig. 15.7](#) illustrates the biological basis of the 3 : 1 ratio of phenotypes that Mendel observed in the  $F_2$  generation. Nevertheless, the underlying ratio of  $AA$  :  $Aa$  :  $aa$  genotypes is 1 : 2 : 1.

FIG. 15.7 The principle of segregation.

## The principle of segregation was tested by predicting the outcome of crosses.

The model of segregation of gene pairs (alleles) and their random combination in the formation of a zygote depicted in [Fig. 15.7](#) was Mendel's hypothesis, an explanation he put forward to explain an observed result. Further experiments were necessary to support or disprove this hypothesis. The true test of a hypothesis is whether it can predict the results of experiments that have not yet been carried out ([Chapter 1](#)). If the predictions are correct, one's confidence in the hypothesis is strengthened. Mendel appreciated this relationship intuitively, even though the scientific method as understood today had not been formalized when he was doing his work.

The Punnett square in [Fig. 15.7](#) makes two predictions. First, it predicts that the seeds in the  $F_2$  generation showing the recessive green seed phenotype should be homozygous  $aa$ , in which case they should breed true. That is, when the seeds are grown into mature plants and self-fertilization is allowed to take place, the self-fertilized  $aa$  plants should produce only green seeds ( $aa$ ). This prediction was confirmed by examining seeds actually produced by plants grown from the  $F_2$  green seeds.

The second prediction from the Punnett square in [Fig. 15.7](#) is more complex: it has to do with the seeds in the  $F_2$  generation that show the dominant yellow phenotype. Although these seeds have the same

phenotype, they have two different genotypes ( $AA$  and  $Aa$ ). Among just the yellow seeds,  $\frac{1}{3}$  should have the genotype  $AA$  and  $\frac{2}{3}$  should have the genotype  $Aa$ , for a ratio of  $1 AA : 2 Aa$ . (The proportions are  $\frac{1}{3} : \frac{2}{3}$  because we are considering *only* the seeds that are yellow.) Plants with the  $AA$  and  $Aa$  genotypes can be distinguished by the types of seed they produce when self-fertilized. The  $AA$  plants produce only seeds with the dominant yellow phenotype (that is, they are true breeding), whereas the  $Aa$  plants yield dominant yellow and recessive green seeds in the ratio  $3 : 1$ . Mendel performed such experiments, and the second prediction turned out to be correct. His data confirming the  $1 : 2$  ratio of  $AA : Aa$  among  $F_2$  individuals with the dominant phenotype are shown in [Table 15.2](#).

**TABLE 15.2 Genetic Ratios from Self-Fertilization of Plants Showing the Dominant Phenotype**

| TRAIT                 | HOMOZYGOUS<br>DOMINANT | HETERO--<br>ZYGOUS | RATIO    |
|-----------------------|------------------------|--------------------|----------|
| Yellow seeds          | 166                    | 353                | 0.94 : 2 |
| Round seeds           | 193                    | 372                | 1.04 : 2 |
| Green pods            | 40                     | 60                 | 1.33 : 2 |
| Smooth pods           | 29                     | 71                 | 0.82 : 2 |
| Purple flowers        | 36                     | 64                 | 1.13 : 2 |

| Tall plants           | 28                     | 72                 | 0.78 : 2 |

**A testcross is a mating to an individual**

## with the homozygous recessive genotype.

A more direct test of segregation is to cross the  $F_1$  progeny with the true-breeding recessive strain instead of allowing them to self-fertilize. Any cross of an unknown genotype with a homozygous recessive genotype is known as a **testcross**.

The  $F_1$  progeny show the dominant yellow seed phenotype. A yellow seed phenotype can result from either of two possible genotypes,  $Aa$  or  $AA$ . A testcross with plants of the homozygous recessive genotype ( $aa$ ) can distinguish between these two possibilities (**Fig. 15.8**).

FIG. 15.8 A testcross. A cross with a homozygous recessive individual reveals the genotype of the other parent.

Let's first consider what happens in a testcross to an  $Aa$  individual (**Fig. 15.8a**). An  $Aa$  individual produces both  $A$ -bearing gametes and  $a$ -bearing gametes. As shown by the Punnett square, the predicted offspring from the testcross between an  $Aa$  parent and an  $aa$  parent are  $\frac{1}{2}$   $Aa$  zygotes, which yield yellow seeds, and  $\frac{1}{2}$   $aa$  zygotes, which

yield green seeds. By contrast, an *AA* individual produces only *A*-bearing gametes, so all the zygotes resulting from a testcross with an *aa* individual have the *Aa* genotype, which yields yellow seeds ([Fig. 15.8b](#)). In other words, the testcross gives different results depending on whether the parent in question is heterozygous (*Aa*) or homozygous (*AA*).

Note that in a testcross the *phenotypes* of the progeny reveal the *alleles* present in the gametes from the tested parent. A testcross with an *Aa* individual yields  $\frac{1}{2}$  *Aa* (yellow seeds) and  $\frac{1}{2}$  *aa* (green seeds) because the *Aa* parent produces  $\frac{1}{2}$  *A*-bearing gametes and  $\frac{1}{2}$  *a*-bearing gametes. A testcross with an *AA* individual yields only *Aa* (yellow seeds) because the *AA* parent produces only *A*-bearing gametes. These results are a direct demonstration of the principle of segregation: the ratio of the phenotypes of progeny reflects the equal segregation of alleles into gametes. Some of Mendel's testcross data indicating 1 : 1 segregation in heterozygous genotypes are shown in [Table 15.3](#).

TABLE 15.3 Phenotype of Progeny from Testcrosses of Heterozygotes

| TRAIT        | DOMINANT TRAIT | RECESSIVE TRAIT | RATIO    |
|--------------|----------------|-----------------|----------|
| Seed color   | 196            | 189             | 1.04 : 1 |
| Seed shape   | 193            | 192             | 1.01 : 1 |
| Flower color | 85             | 81              | 1.05 : 1 |
| Plant height | 87             | 79              | 1.10 : 1 |

Segregation of alleles reflects the separation of chromosomes in meiosis.

The principles of transmission genetics have a physical basis in the process of meiosis ([Chapter 11](#)). During meiosis I, maternal and paternal chromosomes (homologous chromosomes) align on the metaphase plate. Then, during anaphase I, the homologous chromosomes separate, and each chromosome goes to a different pole. Because gene pairs are carried on homologous chromosomes, the segregation of alleles observed by Mendel corresponds to the separation of chromosomes that takes place in anaphase I.

**Fig. 15.9** illustrates the separation of a pair of homologous chromosomes in anaphase I. In the configuration shown, the copies of the *A* allele (dark blue) separate from the copies of the *a* allele (light blue) in anaphase I. The separation of chromosomes is the physical basis of the segregation of alleles.

FIG. 15.9 Segregation of alleles of a single gene. Homologous chromosomes separate during meiosis, leading to segregation of alleles.

## Dominance is not universally observed.

Many traits do not show complete dominance such as Mendel observed with pea plants. Instead, most traits we see are determined by multiple genes or the interaction of genotype and the environment, so they do not display the expected 3 : 1 ratio of phenotypes. But even among traits that are determined by a single gene, the 3 : 1 phenotype ratio is not always observed. In some cases, the trait shows **incomplete dominance**, in which the phenotype of the heterozygous genotype is intermediate between those of the homozygous genotypes. In such cases, the result of segregation can be observed directly because each genotype has a distinct phenotype. An example is flower color in the snapdragon (*Antirrhinum majus*), in which the homozygous genotypes have red ( $C^R C^R$ ) or white ( $C^W C^W$ ) flowers, and the heterozygous genotype  $C^R C^W$  has pink flowers (**Fig. 15.10**). In notating incomplete dominance, we use superscripts to indicate the alleles, rather than uppercase and lowercase letters, because neither allele is dominant to the other. A cross of homozygous  $C^R C^R$  and  $C^W C^W$  strains results in hybrid  $F_1$  progeny that are pink ( $C^R C^W$ ); when these are crossed, the resulting  $F_2$  generation consists of  $\frac{1}{4}$  red ( $C^R C^R$ ),  $\frac{1}{2}$  pink ( $C^R C^W$ ), and  $\frac{1}{4}$  white ( $C^W C^W$ ).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 15.10 Incomplete dominance for flower color in snapdragons. In incomplete dominance, an intermediate phenotype is seen.

In this case, the genotype ratio and the phenotype ratio are both 1 : 2 : 1, because each genotype has a distinct phenotype. Such a direct demonstration of segregation makes one wonder whether Mendel's work might have been appreciated more readily if his traits had shown incomplete dominance!

# The principles of transmission genetics are statistical and are stated in terms of probabilities.

The element of chance in fertilization implies that the genotype of any particular progeny cannot be determined in advance. However, one can deduce the likelihood, or [probability](#), that a specified genotype will occur. The probability of occurrence of a genotype must always lie between 0 and 1; a probability of 0 means that the genotype cannot occur, and a probability of 1 means that the occurrence of the genotype is certain. For example, in the cross  $Aa \times AA$ , no offspring can have the genotype  $aa$ , so in this mating the probability of  $aa$  is 0. Similarly, in the mating  $AA \times aa$ , all offspring must have the genotype  $Aa$ , so in this mating the probability of  $Aa$  is 1.

In many cases, the probability of a particular genotype is neither 0 nor 1, but some intermediate value. For one gene, the probabilities for a single individual can be deduced from the parental genotypes in the mating and the principle of segregation. For example, the probability of producing a homozygous recessive individual from the cross  $Aa \times Aa$  is  $\frac{1}{4}$  (see [Fig. 15.7](#)), and that from the cross  $Aa \times aa$  is  $\frac{1}{2}$  (see [Fig. 15.8a](#)).

The genotype and phenotype probabilities for a single individual can also be inferred from observed data because the overall proportions of two (or more) genotypes among a large number of observations approximate the probabilities of each of the genotypes for a single observation. For example, in Mendel's  $F_2$  data (see [Table 15.1](#)), the

overall ratio of dominant : recessive is 2.98 : 1, or very nearly 3 : 1. This result implies that the probability that an individual  $F_2$  plant has the homozygous recessive phenotype is very close to  $\frac{1}{4}$ , which is the value inferred from the principle of segregation. The reason large samples are important is that the average ratio is more likely to be close to the true ratio in larger samples compared to smaller ones.

Sometimes it becomes necessary to combine the probabilities of two or more possible outcomes of a cross, as in determining the probability of a genotype occurring based on the probabilities of the gametes occurring. In such cases, either of two rules is helpful:

1. **Addition rule.** This principle applies when the possible outcomes being considered cannot occur simultaneously. For example, suppose that a single offspring is chosen at random from the progeny of the mating  $Aa \times Aa$ , and we wish to know the probability that the offspring is either  $AA$  or  $Aa$ . The key words here are “either” and “or.” Each of these outcomes is possible, but both cannot occur simultaneously in a single individual; the outcomes are mutually exclusive. When the possibilities are mutually exclusive, the addition rule states that the probability of either event occurring is given by the sum of their individual probabilities. In this example, the chosen offspring could have either genotype  $AA$  (with probability  $\frac{1}{4}$ , according to [Fig. 15.7](#)) or genotype  $Aa$  (with probability  $\frac{1}{2}$ ). Therefore, the probability that the chosen individual has either the  $AA$  or the  $Aa$  genotype is given by  $\frac{1}{4} + \frac{1}{2} = \frac{3}{4}$  (see [Fig. 15.7](#)). Alternatively, the  $\frac{3}{4}$  probability could be interpreted to mean that, among a large number of offspring from the mating  $Aa \times Aa$ , the proportion

exhibiting the dominant phenotype will be very close to  $\frac{3}{4}$ . This interpretation is verified by the data in [Table 15.1](#).

2. **[Multiplication rule](#)**. This principle applies when outcomes can occur simultaneously, and the occurrence of one has no effect on the likelihood of the other. Events that do not influence one another are independent, and the multiplication rule states that the probability of two independent events occurring together is the product of their respective probabilities. This rule is widely used to determine the probabilities of successive offspring of a cross because each event of fertilization is independent of any other. For example, in the mating  $Aa \times Aa$ , one may wish to determine the probability that, among four peas in a pod, the one nearest the stem is green and the others yellow. Here, the word “and” is a simple indicator that the multiplication rule should be used. Because each seed results from an independent fusion of pollen and ovule, this probability is given by the product of the probability that the seed nearest the stem is  $aa$  and the probability that each of the other seeds is either  $AA$  or  $Aa$ ; hence the probability is  $\frac{1}{4} \times \frac{3}{4} \times \frac{3}{4} \times \frac{3}{4} = 27/256$ .

The addition and multiplication rules are very powerful when used in combination, as seen in [Fig. 15.11](#). Consider the following question: in the mating  $Aa \times Aa$ , what is the probability that, among four seeds in a pod, exactly one is green? We have already seen that the multiplication rule gives the probability of the seed nearest the stem being green as  $27/256$ , as shown for the top pod in [Fig. 15.11](#). As the figure shows, there are only four possible ways in which exactly one seed can be green, each of which has a probability of  $27/256$ , and these outcomes are mutually exclusive. Therefore, by the addition rule, the

probability of there being exactly one green seed and three yellow seeds in a pod, occurring in any order, is given by  $27/256 + 27/256 + 27/256 + 27/256 = 108/256$ , or approximately 42%.

## Mendelian segregation preserves genetic variation.

As noted earlier, Darwin was befuddled because blending inheritance would make genetic variation disappear so rapidly that evolution by means of natural selection could not occur. Although Darwin was completely unaware of Mendel's findings, segregation was the answer to his problem.

An important consequence of segregation is that it demonstrates that the alleles encoding a trait do not alter one another when they are present together in a heterozygous genotype (except in very rare instances). The recessive trait, which is masked in one generation, can appear in the next generation, looking exactly as it did in the true-breeding strains. Mendel fully appreciated the significance of this discovery. In one of his letters, he emphasized that “the two parental traits appear, separated and unchanged, and there is nothing to indicate that one of them has either inherited or taken over anything from the other.” In other words, no hint of any sort of blending between the parental genetic material takes place, so there is no homogenization of the trait in the population. Because the individual genes maintain their identity down through the generations (except for rare mutations), genetic variation in a population also tends to be maintained through time. The maintenance of genetic variation is discussed further in [Chapter 20](#).

#### Self-Assessment Questions

4. What are the genotypes and phenotypes for Mendel’s true-breeding parent plants?
5. Is it possible for two individuals to have the same phenotype but different genotypes? The same genotype, but different phenotypes? How?
6. What is the purpose of a testcross?
7. What is the probability that *any* two seeds are green and two seeds are yellow in a pea pod with exactly four seeds?

## 15.4 INDEPENDENT ASSORTMENT

We have seen that segregation of different alleles of a single gene results in a 3 : 1 ratio of dominant : recessive phenotypes in the  $F_2$  generation. What happens when the parental strains differ in two traits, such as when a strain having yellow and wrinkled seeds is crossed with a strain having green and round seeds? The results of these kinds of experiments constitute Mendel's second key discovery, the **principle of independent assortment**. This principle states that segregation of one set of alleles of a gene pair is independent of the segregation of another set of alleles of a different gene pair. That is, each pair of alleles assorts (segregates) into gametes without affecting or being affected by the assortment of any other pair of alleles.

**Independent assortment is observed when genes segregate independently of one another.**

In the cross between a strain of pea plants with seeds that are yellow and wrinkled and a strain with seeds that are green and round, the phenotype of the  $F_1$  seeds is easily predicted. Because yellow is dominant to green, and round is dominant to wrinkled, the  $F_1$  seeds are expected to be yellow and round, and in fact they are (**Fig. 15.12**).

When these seeds are grown and the  $F_1$  plants are allowed to undergo self-fertilization, the result is as shown in **Fig. 15.12**. Among 639 seeds from this cross, Mendel observed the following:

|                 |     |
|-----------------|-----|
| yellow round    | 367 |
| green round     | 122 |
| yellow wrinkled | 113 |
| green wrinkled  | 37  |

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 15.12 Mendel's crosses with two traits. Plants heterozygous for two genes affecting different traits produce offspring with a phenotypic ratio of 9 : 3 : 3 : 1.

The ratio of these phenotypes is 9.9 : 3.3 : 3.1 : 1.0, which Mendel realized is close to 9 : 3 : 3 : 1. The latter ratio is that expected if the *A* and *a* alleles for seed color undergo segregation and form gametes independently of the *B* and *b* alleles for seed shape. How did Mendel come to expect a 9 : 3 : 3 : 1 ratio of phenotypes? For seed color alone, we expect a ratio of  $\frac{3}{4}$  yellow :  $\frac{1}{4}$  green; for seed shape alone, we expect a ratio of  $\frac{3}{4}$  round :  $\frac{1}{4}$  wrinkled. If the traits are independent, then we can use the multiplication rule to predict the outcomes for both traits:

|                 |                                             |
|-----------------|---------------------------------------------|
| yellow round    | $(\frac{3}{4}) \times (\frac{3}{4}) = 9/16$ |
| green round     | $(\frac{1}{4}) \times (\frac{3}{4}) = 3/16$ |
| yellow wrinkled | $(\frac{3}{4}) \times (\frac{1}{4}) = 3/16$ |
| green wrinkled  | $(\frac{1}{4}) \times (\frac{1}{4}) = 1/16$ |

Note that 9/16 : 3/16 : 3/16 : 1/16 is equivalent to 9 : 3 : 3 : 1.

The underlying reason for the 9 : 3 : 3 : 1 ratio of phenotypes in the  $F_2$  generation is that the alleles for yellow versus green and those for round versus wrinkled are assorted into gametes independently of each other. In other words, the hereditary transmission of either gene has no effect on the hereditary transmission of the other gene. A Punnett square depicting independent assortment is shown in [Fig. 15.13](#). The *A* and *a* alleles segregate equally into gametes as  $\frac{1}{2} A : \frac{1}{2} a$ , and likewise the *B* and *b* alleles segregate equally into gametes as  $\frac{1}{2} B : \frac{1}{2} b$ . The result of independent assortment is that the four possible gametic types are produced in equal proportions:

|                   |                                                    |
|-------------------|----------------------------------------------------|
| <i>AB</i> gametes | $(\frac{1}{2}) \times (\frac{1}{2}) = \frac{1}{4}$ |
| <i>Ab</i> gametes | $(\frac{1}{2}) \times (\frac{1}{2}) = \frac{1}{4}$ |
| <i>aB</i> gametes | $(\frac{1}{2}) \times (\frac{1}{2}) = \frac{1}{4}$ |
| <i>ab</i> gametes | $(\frac{1}{2}) \times (\frac{1}{2}) = \frac{1}{4}$ |

As the Punnett square in [Fig. 15.13](#) shows, random union of these gametic types produces the expected ratio of 9 yellow round, 3 green round, 3 yellow wrinkled, and 1 green wrinkled. [Fig. 15.14](#) summarizes how Mendel's experiments led him to formulate his two laws.

#### HOW DO WE KNOW?

### FIG. 15.14

## How are single-gene traits inherited?

#### BACKGROUND

Gregor Mendel's experiments, carried out in the years 1856–1863, are among the most important in all of biology. Mendel set out to improve upon previous research in heredity. He wrote that “among all the numerous experiments made, not one has been carried out to such an extent and in such a way as to make it possible to determine the number of different forms under which the offspring of the hybrids appear, or to arrange these forms with certainty according to their separate generations, or definitely to ascertain their numerical relations.”

#### METHOD

By studying simple traits across successive generations of crosses, Mendel observed how various traits are transmitted to find out whether there were regular and reproducible quantitative relations among the various phenotypes.

#### HYPOTHESIS

By keeping track of the ancestral history of the parents in a mating, Mendel hypothesized that the phenotypes of the offspring could be predicted and their relative frequencies would obey certain “numerical relations.”

#### RESULTS

Crosses between plants that were hybrids of a single trait displayed two phenotypes in a ratio that averaged 3 : 1, with variation from experiment to experiment due purely to chance. Similarly, crosses between plants that were hybrids of two traits displayed four different phenotypes in a ratio averaging 9 : 3 : 3 : 1, again with variation among experiments due to

chance.

## CONCLUSION

From observing these ratios among several different traits, Mendel came up with two conclusions about the inheritance of the genetic factors underlying traits, which are now called Mendel's laws:

1. The principle of segregation states that individuals inherit two copies (alleles) of each gene, one from the mother and one from the father. When the individual then forms reproductive cells, the two copies separate (segregate) equally in the eggs or sperm.

2. The principle of independent assortment states that the two copies of each gene segregate into gametes independently of the two copies of another gene.

## ANALYSIS

Mendel found support for his two conclusions in the statistical analysis of the results of his meticulous crosses.

1. The principle of segregation: A prediction of the hypothesis of segregation is that, among seeds with the dominant phenotype, the ratio of homozygous to heterozygous genotypes should be 1 : 2. Mendel tested this prediction in several ways, one of which was simply to allow plants grown from  $F_2$  seeds to self-fertilize. Any that were true breeding for the dominant phenotype he classified as homozygous, and any that segregated to yield both dominant and recessive phenotypes he classified as heterozygous. In the experimental test, the observed numbers fit the expected values within the margins that would be expected by chance.

| Experimental test                                                                   |                                                                                           |                                                                                           |
|-------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------|-------------------------------------------------------------------------------------------|
|                                                                                     | <br>AA | <br>Aa |
| Observed                                                                            | 166                                                                                       | 353                                                                                       |
| Expected                                                                            | 173                                                                                       | 346                                                                                       |
| Morris, <i>Biology: How Life Works</i> ,<br>3e, © 2019 W. H. Freeman and<br>Company |                                                                                           |                                                                                           |

2. The principle of independent assortment: Although the Punnett square for two pairs of alleles has 16 squares, there are only 9 genotypes, and the hypothesis of independent assortment predicts that these genotypes should appear in the ratios of  
1 AA BB : 2 AA Bb : 1 AA bb : 2 Aa BB and  
4 Aa Bb : 2 Aa bb : 1 aa BB : 2 aa Bb : 1 aa bb. As before, Mendel tested this hypothesis by self-fertilization of plants grown from the  $F_2$  seeds, classifying any that bred true for either trait as homozygous and any that segregated to yield both dominant and recessive phenotypes as heterozygous. In the experimental test, once again the observed numbers fit the expected values within the margins that would be expected by chance.

**FOLLOW-UP WORK**

Mendel's work was ignored during his lifetime, and its importance was not recognized until 1900, 16 years after his death. The rediscovery marks the beginning of the modern science of genetics.

SOURCE Mendel's paper in English is available at <http://www.mendelweb.org/Mendel.html>.

## Independent assortment reflects the random alignment of chromosomes in meiosis.

Independent assortment of genes on different chromosomes results from the mechanics of meiosis ([Chapter 11](#)), in which different pairs of homologous chromosomes align randomly on the metaphase plate in meiosis I. For some pairs of chromosomes, the maternal chromosome goes toward one pole during anaphase I, and the paternal chromosome goes to the other pole; for other pairs, just the opposite occurs. Because the alignment is random, gene pairs on different chromosomes assort

independently of one another.

**Fig. 15.15** illustrates two possible alignments that are equally likely. In one alignment, the *B* allele (dark red) goes to the same pole as the *A* allele (dark blue); in the other alignment, the *b* allele (light red) goes in the same direction as the *A* allele. The first type of alignment results in a 1 : 1 ratio of *AB* : *ab* gametes, and the second type of alignment results in a 1 : 1 ratio of *Ab* : *aB* gametes. Because the two orientations are equally likely, the overall ratio of *AB* : *ab* : *Ab* : *aB* from a large number of cells undergoing meiosis is expected to be 1 : 1 : 1 : 1. This is the principle of independent assortment for genes located in different chromosomes.

FIG. 15.15 Independent assortment of genes in different chromosomes. Chromosome pairs are sorted into daughter cells randomly during meiosis I, resulting in independent assortment of genes.

Not all genes undergo independent assortment. For example, genes near one another in the same chromosome do not assort independently of one another. Genes in the same chromosome that fail to show independent assortment are said to be linked and are discussed in [Chapter 16](#).

## Phenotypic ratios can be modified by interactions between genes.

The 9 : 3 : 3 : 1 ratio of phenotypes results from independent assortment of two genes when one allele of each gene is dominant and when the two genes affect different traits. However, even with complete dominance, the ratio of phenotypes may be different if the two genes affect the same trait. This often happens when the genes code for proteins that act in the same biochemical pathway. In such cases, the gene products can interact to affect the phenotypic expression of the genotypes, resulting in a modification of the expected ratio. Genes that modify the phenotypic expression of other genes are said to show [epistasis](#).

There are many types of epistasis, leading to different modifications of the 9 : 3 : 3 : 1 ratio. Among the more common modified ratios are 12 : 3 : 1, as well as 9 : 3 : 4 and 13 : 3. [Fig. 15.16](#) shows one example, in which the F<sub>2</sub> generation of a cross between White Leghorn and

White Wyandotte chickens displays the modified ratio 13 : 3. Both breeds are white, but for different genetic reasons. There are two genes involved in pigment production, each with two alleles. The *C* gene encodes a protein that affects coloration in feathers ([Fig. 15.16a](#)). The dominant allele *C* produces pigment, and the recessive allele *c* does not produce pigment. A different gene, *I*, codes for an inhibitor protein. The product of the dominant allele, *I*, inhibits the expression of *C*, whereas the recessive allele, *i*, does not produce the inhibitor and so does not inhibit the expression of *C*. Therefore, the White Leghorn (genotype *CC II*) is white because the product of the dominant allele *I* inhibits the pigment in the feathers, and the White Wyandotte (genotype *cc ii*) is white because the recessive allele *c* does not produce feather pigment to begin with. The  $F_1$  generation has genotype *Cc Ii* and is also white. With independent assortment, only the three *C–ii* offspring have colored feathers in the  $F_2$  generation (the dash indicates that the second allele could be either *C* or *c*). The rest have white feathers, so the ratio of white : colored is 13 : 3 ([Fig. 15.16b](#)).

a.

b.

The White Leghorn is white because the inhibitor allele *I* blocks expression of the pigment allele *C*.

The White Wyandotte is white because the pigment allele *c* does not produce pigment.

Genotypes of the form *C- ii* have colored feathers, whereas all other genotypes have white feathers. The result is an F<sub>2</sub> ratio of white:colored of 13:3, which is a modified form of the expected 9:3:3:1.

#### Alleles

- C Pigment
- c No pigment
- I Inhibitor
- i No inhibitor

FIG. 15.16 Epistasis, the interaction of genes affecting the same trait. Epistasis can modify the 9 : 3 : 3 : 1 ratio of phenotypes, in this example to 13 : 3.

#### Self-Assessment Questions

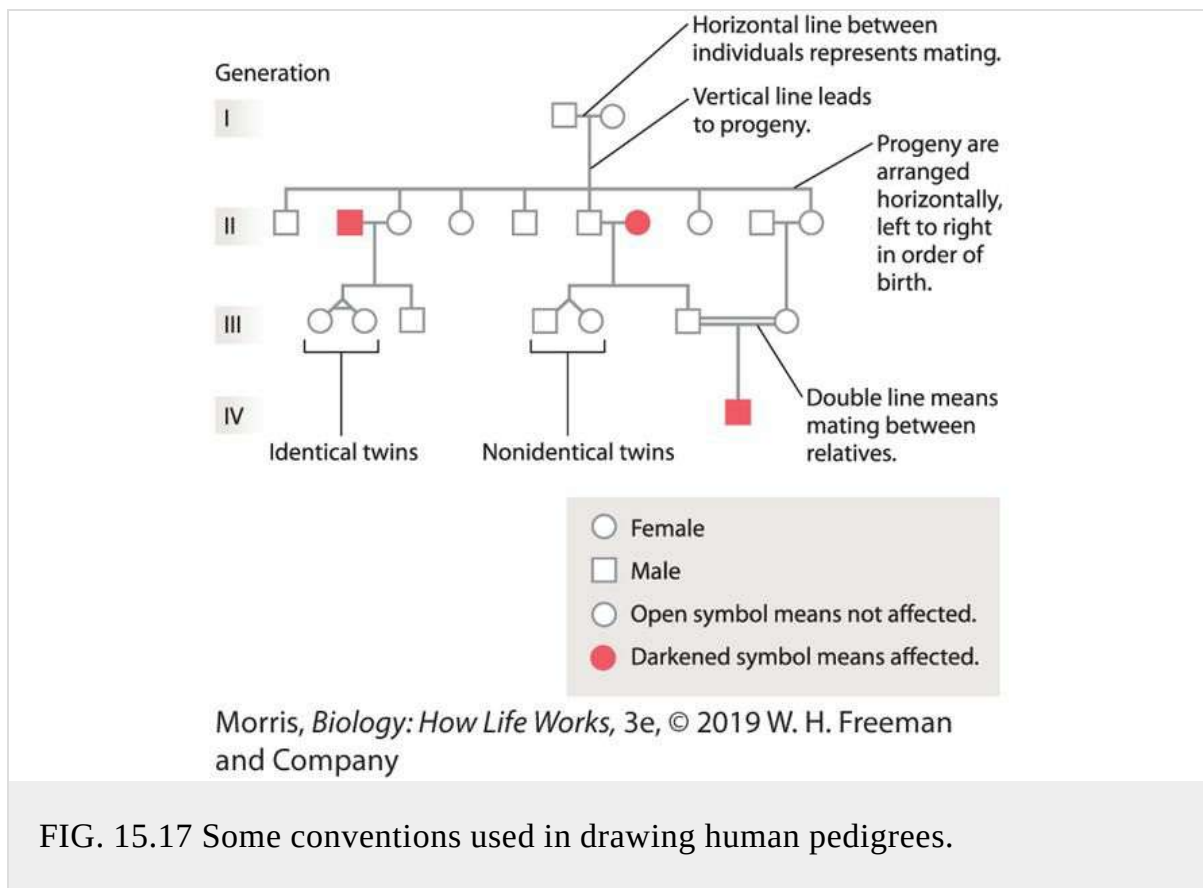

8. What are Mendel's two laws?
9. How do the mechanics of meiosis and the movement of homologous chromosomes underlie Mendel's principles of segregation and independent assortment?
10. How can you predict the genotypes and phenotypes of offspring if you know the genotypes of the parents?
11. What are some reasons why a single trait might not show a 3 : 1 ratio of phenotypes in the  $F_2$  generation of a cross between true-breeding strains, and why a pair of traits might not show a 9 : 3 : 3 : 1 ratio of phenotypes in the  $F_2$  generation of a cross between true-breeding strains?

## 15.5 HUMAN GENETICS

Segregation of alleles takes place in human meiosis, just as it does in peas and most other sexual organisms. Nevertheless, the results are not so easily observed as in peas, for several reasons. First, humans do not choose their mating partners for the convenience of biologists, so experimental crosses are not possible. Second, the number of children in human families is relatively small, so the Mendelian ratios are often obscured by random fluctuations due to chance. Even so, in many cases segregation can be observed in human families.

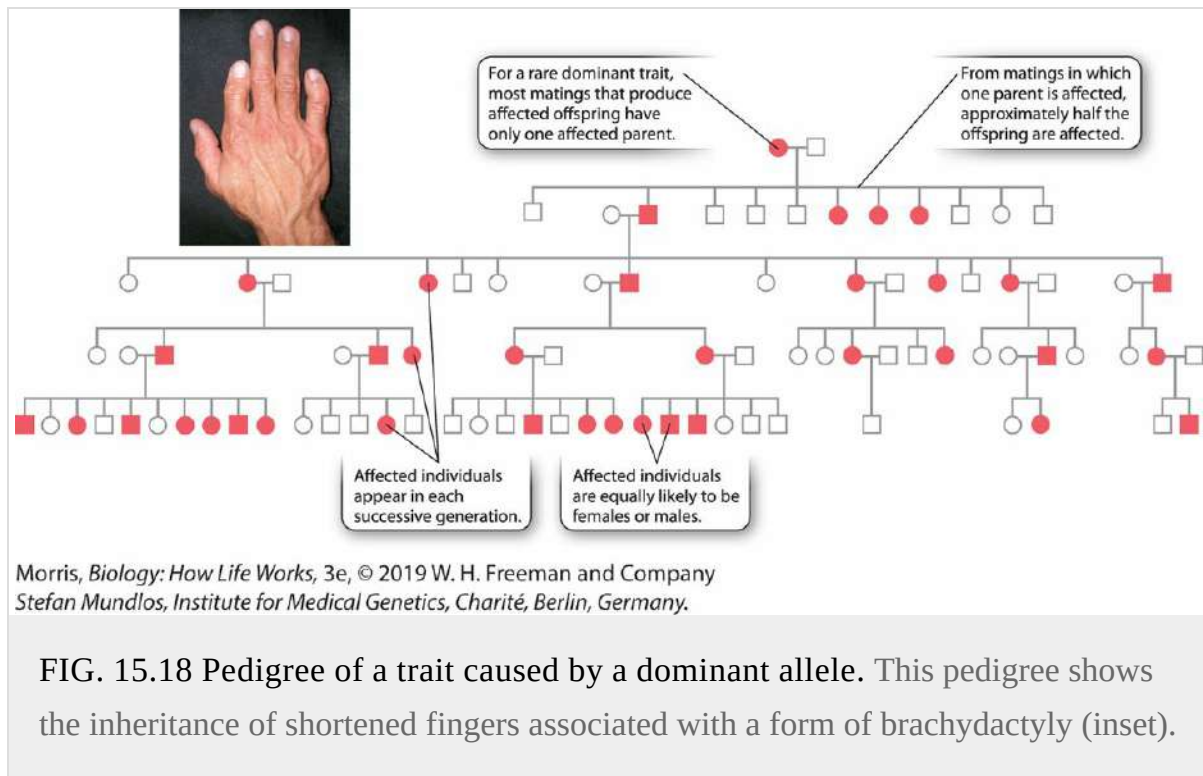

In studying human families, the record of the ancestral relationships among individuals is summarized in a diagram of family history called a **pedigree**. Some typical symbols used in pedigrees are shown in **Fig. 15.17**. The same patterns of dominance and recessiveness that Mendel observed in his pea plants can be seen in some pedigrees. Over the next few sections, we'll see how to recognize telltale features of a pedigree that reveal the genotypic nature of a trait.

## Dominant traits appear in every generation.

The pedigree shown in [Fig. 15.18](#) is for a rare dominant trait, brachydactyly, in which the middle long bone in the fingers fails to grow, such that the fingers remain very short. This pedigree, published in 1905, was the first demonstration of dominant Mendelian inheritance in humans. This particular form of brachydactyly results from a mutation in a gene whose normal product is a protein involved in cartilage formation, which is necessary for bone growth.

These are the features of the pedigree that immediately suggest dominant inheritance:

1. Affected individuals are equally likely to be females or males.
2. Most matings that produce affected offspring have only one affected parent. The brachydactyly trait is rare, so a mating between two affected individuals is extremely unlikely.
3. Among matings in which one parent is affected, approximately half the offspring are affected.

If a dominant trait is rare, then affected individuals will almost always be heterozygous ( $Aa$ ), not homozygous ( $AA$ ). In a mating in which one parent is heterozygous for the dominant gene ( $Aa$ ) and the other is homozygous recessive ( $aa$ ), half the offspring are expected to be heterozygous ( $Aa$ ) and the other half homozygous recessive ( $aa$ ).

## Recessive traits skip generations.

Recessive inheritance shows a pedigree pattern very different from that of dominant inheritance. The pedigree shown in [Fig. 15.19](#) pertains to albinism, in which the amount of melanin pigment in the skin, hair, and eyes is reduced. In most populations, the frequency of albinism is about 1 in 36,000, but it has a much higher frequency—about 1 in 200—among the Hopi and several other Native American tribes of the Southwest. (It is not unusual for genetic diseases to have elevated frequencies among isolated populations.) This type of albinism is due to a mutation in the gene *OCA2*, which encodes a membrane transporter protein thought to be important in transport of the amino acid tyrosine, which is used in the synthesis of the melanin pigment responsible for skin, hair, and eye color.

Another type of mutation affecting expression of this same gene is associated with blue eyes. As shown in [Fig. 15.19](#), double lines represent matings between relatives, and in both cases shown here the mating is between first cousins.

These are the principal pedigree characteristics of recessive traits:

1. The trait may skip one or more generations.
2. Affected individuals are equally likely to be females or males.
3. Affected individuals may have unaffected parents, as in the offspring of the second mating in the second generation in [Fig. 15.19](#). For a recessive trait that is sufficiently rare, almost all affected individuals have unaffected parents.
4. Affected individuals often result from mating between relatives, typically first cousins.

Recessive inheritance has these characteristics because recessive alleles can be transmitted from generation to generation without manifesting the recessive phenotype. For an individual to be affected, that person must inherit the recessive allele from both parents. Mating between relatives often allows rare recessive alleles to become homozygous because an ancestor shared between the relatives may carry the gene ( $Aa$ ). The recessive allele in the common ancestor can be transmitted to both parents, making them each a carrier of the allele as well. If both parents are unaffected carriers of the allele, they both have the genotype  $Aa$ , and  $\frac{1}{4}$  of their offspring are expected to be homozygous  $aa$  and affected.

## Many genes have multiple alleles.

The examples discussed so far in this chapter involve genes with only two alleles, such as  $A$  for yellow seeds and  $a$  for green seeds. Similarly, as noted in [Chapter 14](#), most single-nucleotide polymorphisms (SNPs) have only two alleles, differing only in which particular base pair is present at a particular position in genomic DNA. In contrast, because a

gene consists of a sequence of nucleotides, any nucleotide or set of nucleotides in the gene can undergo mutation. Because each of the mutant forms that exists in a population constitutes a different allele, a population of organisms may contain many different alleles of the same gene, which are called **multiple alleles**. Some genes have so many alleles that they can be used for individual identification by means of DNA typing, as discussed in [Chapter 14](#).

In considering genetic diseases, multiple alleles are often grouped into categories such as “mutant” and “normal.” But there are often many different “mutant” alleles and many different “normal” alleles in a population. For the “mutant” alleles, the DNA sequences are different from one another, but each produces a protein product whose function is impaired under the usual environmental conditions. For the “normal” alleles, the DNA sequences are also different, but they all are able to produce functional protein.

For example, more than 400 different recessive alleles of the gene that causes phenylketonuria (PKU) have been discovered across the world. PKU is a moderate to severe form of mental retardation caused by mutations in the gene encoding the enzyme phenylalanine hydroxylase. Children affected with PKU are unable to break down the excess phenylalanine present in a normal diet, and the buildup impairs the development of neurons in the brain. About 1 in 10,000 newborns inherits two mutant alleles, which could be two copies of the same mutant allele or two different mutant alleles, and is affected. The “normal” form of the gene encoding phenylalanine hydroxylase also exists in the form of multiple alleles, each of which differs from the

others, but nevertheless encodes a functional form of the enzyme.

## Incomplete penetrance and variable expression can obscure inheritance patterns.

Many traits with single-gene inheritance demonstrate complications that can obscure the expected patterns in pedigrees. Chief among these are traits with [incomplete penetrance](#), which means that individuals with a genotype corresponding to a trait do not actually show the phenotype, either because of environmental effects or because of interactions with other genes. Penetrance is the proportion of individuals with a particular genotype that show the expected phenotype. If the penetrance is less than 100%, then the trait shows reduced, or incomplete, penetrance.

For example, type 2 diabetes is associated with certain mutations in the gene *TCF7L2* that affect insulin secretion and glucose production, but the mutations are not completely penetrant. That is, some people who inherit a *TCF7L2* risk factor for type 2 diabetes do not actually develop the disease because environmental factors are also important in the causation of the disease. In other words, the genetic risk associated with the mutant forms of *TCF7L2* can often be offset by lifestyle choices such as proper diet and exercise. Similarly, familial cancers also often show incomplete penetrance.

Another common complication in human pedigrees is [variable expressivity](#), which means that a particular phenotype is expressed

with a different degree of severity in different individuals. Don't confuse variable expressivity with incomplete penetrance. With variable expressivity, the trait is always expressed, though the severity varies; with incomplete penetrance, the trait is sometimes expressed and sometimes not. Variation among individuals in the expression of a trait can result from the action of other genes, from effects of the environment, or both. An example is provided by deficiency of the enzyme alpha-1 antitrypsin ( $\alpha$ 1AT) discussed in [Chapter 14](#), which is associated with loss of lung elasticity and emphysema. Among individuals with emphysema due to  $\alpha$ 1AT deficiency, the severity of the symptoms varies dramatically from one patient to the next. In this case, tobacco smoking is an environmental factor that increases the severity of the disease.

Incomplete penetrance and variable expressivity both provide examples where a given genotype does not always produce the same phenotype, since the expression of genes is often influenced by other genes, the environment, or a combination of the two.

### CASE 3 YOUR PERSONAL GENOME: YOU, FROM A TO T

## How do genetic tests identify disease risk factors?

Your personal genome, as well as that of every human being, contains a unique combination of alleles of thousands of different genes. Most

of these have no detectable effects on health or longevity, but as we saw in [Chapter 14](#), many are risk factors for genetic diseases. Molecular studies have discovered particular alleles of genes associated with a large number of such conditions, and the presence of these alleles can be tested. More than a thousand genetic tests have already been deployed, and many more are actively being developed. A [genetic test](#) is a method of identifying the genotype of an individual. An example of genetic testing is the DNA fingerprinting used in criminal investigations ([Chapter 14](#)). In genetic tests for risk factors for disease, the tests may be carried out on entire populations or they may be restricted to high-risk individuals.

The benefits of genetic testing can be appreciated by an example. Screening of newborns for phenylketonuria identifies babies with high blood levels of phenylalanine. In the absence of treatment, 95% of such newborns will progress to moderate or severe mental retardation, whereas virtually all those placed on a special diet with a controlled amount of phenylalanine will have mental function within the normal range. For recessive conditions like phenylketonuria, tests can be carried out on people with affected relatives to identify the heterozygous genotypes. Testing can also identify genetic risk factors for disease, and carriers can take additional precautions. For example, individuals who are found to have an  $\alpha 1$ AT deficiency can prolong and improve the quality of their lives by not smoking tobacco, women with the genetic risk factors *BRCA1* and *BRCA2* for breast cancer can have frequent mammograms, and those with the *TCF7L2* risk factor for type 2 diabetes can decrease their risk by making lifestyle choices that include weight control and exercise.

While genetic testing has many potential benefits, it also has some perils. One major concern is maintaining the privacy of those persons who choose to be tested. With medical records increasingly going online, who will have access to your test results, and how will this information be used? Could your test results be used to deny you health or life insurance because you have a higher than average risk of some medical condition? Could an employer who got hold of your genetic test results decide to reassign you to another job, or even eliminate your position because of your genetic predispositions? Some safeguards have already been designed to protect you from such discrimination. The Genetic Information Nondiscrimination Act (GINA), which was signed into law in 2008, forbids the use of genetic information in decisions concerning employment and health insurance. The protection provided by GINA will, it is hoped, allow for the responsible and productive use of genetic information.

There is also increasing concern about the reliability and accuracy of genetic tests, especially direct-to-consumer (DTC) genetic tests. DTC tests can be purchased directly without the intervention of medical professionals. Because the consumer sends a biological sample and DTC tests are carried out by the provider, these tests are not regarded as medical devices and so are unregulated, which leads to some problems. Unfortunately, some DTC tests are based on flimsy and unconfirmed evidence connecting a gene with a disease. In addition, the link between genotype and risk may sometimes be exaggerated by the testing company for marketing purposes. Yet another problem is lack of information on quality control in the DTC laboratories. Finally, consumer misinterpretation may regard genotype

as destiny, at one extreme descending into depression and despair, and at the other extreme using a low-risk genotype to justify an unhealthy lifestyle.

#### Self-Assessment Questions

12. How is it possible that there are multiple different alleles in a population, yet any individual can have only two alleles?
13. Construct a human pedigree for a dominant trait and a recessive trait. What are the patterns of inheritance in each?
14. What are some of the benefits and risks of genetic testing and personal genomics?

## CORE CONCEPTS SUMMARY

**15.1 EARLY THEORIES OF INHERITANCE:** Early theories of heredity incorrectly assumed the inheritance of acquired characteristics and blending of parental traits in the offspring.

The inheritance of acquired characteristics suggests that traits that develop during the lifetime of an individual can be passed on to offspring. With rare exceptions, this mode of inheritance does not occur. [page 323](#)

Blending inheritance is the incorrect hypothesis that characteristics in the parents are averaged in the offspring. This model predicts the blending of genetic material, which does not occur. Different forms of a gene maintain their separate identities even when present together in the same individual. [page 324](#)

## 15.2 FOUNDATIONS OF MODERN TRANSMISSION

**GENETICS:** The study of modern transmission genetics began with Gregor Mendel, who used the garden pea and studied traits with contrasting characteristics.

Mendel started his experiments with true-breeding plants, ones whose progeny are identical to their parents. He followed just one or two traits at a time, allowing him to discern simple patterns, and he counted all the progeny of his crosses. [page 325](#)

In crosses of one true-breeding plant with a particular trait and another true-breeding plant with a contrasting trait, just one of the two characteristics appeared in the offspring. The trait that

appeared in this generation is dominant, and the trait that is not seen is recessive. [page 326](#)

Mendel explained this result by hypothesizing that there is a hereditary factor for each trait (now called a gene); that each pea plant carries two copies of the gene for each trait; and that one of two different forms of the gene (alleles) is dominant to the other one. [page 327](#)

**15.3 SEGREGATION:** Mendel's first key discovery was the principle of segregation, which states that members of a gene pair separate equally into gametes.

When Mendel allowed the progeny of the first cross to self-fertilize, he observed a 3 : 1 ratio of the dominant and recessive traits among the progeny. [page 328](#)

Mendel reasoned that the parent in this generation must have two different forms of the same gene ( $A$  and  $a$ ) and that these alleles segregate from each other during gamete formation, with each gamete getting  $A$  or  $a$ , but not both. When the gametes combine at random during fertilization, they produce progeny in the genotypic ratio 1  $AA$  : 2  $Aa$  : 1  $aa$ , which yields a phenotypic ratio of 3 : 1 because  $A$  is dominant to  $a$ . This idea became known as the principle of segregation. [page 328](#)

The principle of segregation reflects the separation of homologous chromosomes that occurs in anaphase I of meiosis. [page 330](#)

Some traits show incomplete dominance, in which the phenotype of the heterozygous genotype is intermediate between the phenotypes

of the two homozygous genotypes. [page 331](#)

The expected frequencies of progeny of crosses can be predicted using the addition rule, which states that when two possibilities are mutually exclusive, the probability of either event occurring is the sum of their individual probabilities; and the multiplication rule, which states that when two possibilities occur independently, the probability of both events occurring is the product of the probabilities of each of the two events. [page 332](#)

**15.4 INDEPENDENT ASSORTMENT:** Mendel's second key discovery was the principle of independent assortment, which states that different gene pairs segregate independently of one another.

In a cross with two traits, each with two contrasting characteristics, the two traits behave independently of each other. This idea became known as the principle of independent assortment. For example, in a self-cross of a double heterozygote, the phenotypic ratio of the progeny is 9 : 3 : 3 : 1, reflecting the independent assortment of two 3 : 1 ratios. [page 333](#)

Independent assortment results from chromosome behavior during meiosis, specifically from the random orientation of different chromosomes on the meiotic spindle. [page 334](#)

In some cases, genes interact with each other, modifying the expected ratios in crosses. Epistasis is a gene interaction in which one gene affects the expression of another. [page 334](#)

**15.5 HUMAN GENETICS:** The patterns of inheritance that Mendel

observed in peas can also be seen in humans.

In a human pedigree, females are represented by circles and males as squares; affected individuals are shown as filled symbols and unaffected individuals as open symbols. Horizontal lines denote matings. [page 337](#)

Dominant traits appear in every generation and affect males and females equally. [page 337](#)

Recessive traits skip one or more generations and affect males and females equally. Affected individuals often result from matings between close relatives. [page 337](#)

Although a given individual has only two alleles of each gene, there can be many alleles of a particular gene in the population as a whole. [page 339](#)

Interpreting pedigrees can be difficult because of incomplete penetrance and variable expressivity. Penetrance is the percentage of individuals with a particular genotype who show the expected phenotype, and expressivity is the degree to which a genotype is expressed in the phenotype. [page 339](#)

Genetic testing enables the genotype of an individual to be determined for one or more genes. Such tests carry both benefits and risks. [page 339](#)

## CHAPTER 16 Inheritance of Sex Chromosomes, Linked Genes, and Organelles

FatCamera/Getty Images

---

## CORE CONCEPTS

**16.1 THE X AND Y CHROMOSOMES:** Many organisms have a distinctive pair of chromosomes that differ between the sexes and show different patterns of inheritance from other chromosomes.

**16.2 INHERITANCE OF GENES IN THE X CHROMOSOME:** X-linked genes show a crisscross inheritance pattern.

**16.3 GENETIC LINKAGE:** Genes that are close together in the same chromosome tend to remain together in inheritance.

**16.4 INHERITANCE OF GENES IN THE Y CHROMOSOME:** Most Y-linked genes are passed from father to son.

**16.5 INHERITANCE OF MITOCHONDRIAL AND CHLOROPLAST DNA:** Mitochondria and chloroplast DNA follow their own inheritance pattern.

---

Mendel's principles of segregation and independent assortment are the foundation of transmission genetics ([Chapter 15](#)). For traits such as pea color and seed shape that are encoded by single genes and display simple dominance, these principles predict simple phenotypic ratios in the progeny from self-crosses of heterozygous genotypes.

However, we also saw in [Chapter 15](#) that not all crosses are as simple as those for Mendel's pea plants. For example, in the case of alleles that show incomplete dominance, the 3 : 1 phenotypic ratio in progeny of self-crosses of heterozygotes is 1 : 2 : 1. The 9 : 3 : 3 : 1 ratio of phenotypes observed for two genes that show independent assortment can be altered by epistasis, producing ratios such as

12 : 3 : 1 or 13 : 3. None of these is an exception to Mendel's laws because his laws reflect chromosome movement during meiosis ([Chapter 11](#)). Instead, they reflect how genes are expressed or how different genes interact to produce a phenotype.

This chapter highlights additional patterns of inheritance that Mendel did not observe because of his choice of experimental organism and the traits he studied. None of these patterns undermines or invalidates his insights, nor do they contradict later discoveries that genes in the nucleus are present in homologous chromosomes that pair and segregate in meiosis. Since Mendel's time, researchers have observed many inheritance patterns that seem to defy one or both of Mendel's laws. What such examples reveal is that the location of a gene is as important to our predictions about the inheritance of a trait as whether its alleles are dominant or recessive.

In this chapter, we discuss how genes carried in the sex chromosomes are transmitted differently in males and in females and how genes close to each other in the same chromosome do not undergo independent assortment and therefore violate Mendel's second law. Genes located in the genomes of mitochondria and chloroplast appear to defy Mendel's laws altogether because the organelles are inherited differently from the way chromosomes are inherited. Such unique patterns of inheritance expand the types of ratios and predictions we saw in [Chapter 15](#) and draw our attention to the location and organization of genes—in specific chromosomes, relative to other genes, or outside the nucleus altogether.

## 16.1 THE X AND Y CHROMOSOMES

Mendel concluded from his experiments that reciprocal crosses yield the same types of progeny in the same proportions. This is in most cases true, but an important exception occurs with the *X* and *Y* sex chromosomes. For example, red–green color blindness in humans is due to mutant alleles of a gene in the *X* chromosome. Reciprocal crosses do not produce the same types and numbers of progeny. When a color-blind man mates with a woman who is not color blind, all of the sons and daughters have normal color vision. However, in the reciprocal cross, when a color-blind woman mates with a man who is not color blind, all of the daughters have normal color vision but all of the sons are color blind. For the *X* and *Y* sex chromosomes, reciprocal crosses are not equivalent.

**In many animals, sex is genetically determined and associated with chromosomal differences.**

Most chromosomes come in pairs that match in shape and size. The members of each pair are known as homologous chromosomes because they have the same genes along their length ([Chapter 11](#)). One member of each pair of homologous chromosomes is inherited from the mother and the other from the father. In many animal species, however, the sex of an individual is determined by a distinctive pair of unmatched chromosomes known as the **sex chromosomes**, which are usually designated as the ***X* chromosome** and the ***Y* chromosome** ([Chapter](#)

[13](#)). Chromosomes other than the sex chromosomes are known as **autosomes**.

In humans, a normal female has two copies of the *X* chromosome (a sex-chromosome constitution denoted *XX*), and a normal male has one *X* chromosome and one *Y* chromosome (*XY*). As seen in [Fig. 16.1](#), the sizes of the human *X* and *Y* chromosomes are very different from each other. The *X* chromosome DNA molecule is more than 150 Mb long, whereas the *Y* chromosome is only about 50 Mb long. Except for a small region near each tip (red in [Fig. 16.1](#)), the gene contents of the *X* and *Y* chromosomes differ from each other. The *X* chromosome, which includes more than 1000 genes, has a gene density similar to that of most autosomes. Most of these genes have no counterpart in the *Y* chromosome. In contrast to the *X* chromosome, the *Y* chromosome contains only about 50 protein-coding genes.

Source: Science Photo Library/Science Source.

FIG. 16.1 Human sex chromosomes. The human *X* and *Y* sex chromosomes differ in size and number of genes.

The regions of homology between the *X* and *Y* chromosomes consist of about 2.7 Mb of DNA near the tip of the short arm and about 0.3 Mb of DNA near the tip of the long arm. These regions of homology allow the chromosomes to pair during meiosis ([Chapter 11](#)). In most cells undergoing meiosis, a **crossover** (physical breakage, exchange of parts, and rejoining of the DNA molecules) occurs in the larger of these regions. The crossover allows the chromosomes to move as a unit to align properly at metaphase I so that, when their centromeres separate from each other at anaphase I, the *X* and *Y* chromosomes go to opposite poles.

The relative size and gene content of the *X* and *Y* chromosomes

differ greatly among species. In some species of mosquitoes, the *X* and *Y* chromosomes are virtually identical in size and shape, and the regions of homology include almost the entire chromosome. This situation is unusual, however. In most species, the *Y* chromosome contains many fewer genes than the *X* chromosome. Some species, such as grasshoppers, have no *Y* chromosome: females in these species have two *X* chromosomes and males have only one *X* chromosome. The total number of chromosomes in grasshoppers, therefore, differs between females and males. In birds, moths, and butterflies, the sex chromosomes are reversed: Females have two different sex chromosomes and males have two of the same sex chromosome.

## Segregation of the sex chromosomes predicts a 1 : 1 ratio of females to males.

It is ironic that Mendel did not interpret sex as an inherited trait. If he had, he might have realized that sex itself provides one of the most convincing demonstrations of segregation. In human males, segregation of the *X* chromosome from the *Y* chromosome during anaphase I of meiosis results in half the sperm bearing an *X* chromosome and the other half bearing a *Y* chromosome ([Fig. 16.2](#)). Meiosis in human females results in eggs that each contains one *X* chromosome. With random fertilization, as shown in [Fig. 16.2](#), half of the fertilized eggs are expected to be chromosomally *XX* (and therefore female) and half are expected to be chromosomally *XY* (and therefore male).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 16.2 Inheritance of the X and Y chromosomes. Segregation of the sex chromosomes in meiosis and random fertilization result in a 1 : 1 ratio of female : male embryos.

The expected ratio of 1 : 1 of females : males refers to the sex ratio at the time of conception. This is the primary sex ratio, and it is not easily observed because the earliest stages of human fertilization and development are inaccessible to large-scale study. What can be observed is the sex ratio at birth, called the secondary sex ratio, which differs among populations but usually shows a slight excess of males. In the United States, for example, the secondary sex ratio is approximately 100 females : 105 males. The explanation seems to be

that, for reasons that are not entirely understood, female embryos are slightly less likely to survive from conception to birth. On the other hand, males are slightly less likely to survive from birth to reproductive maturity, and so, at the age of reproductive maturity, the sex ratio is very nearly 1 : 1. Male mortality continues to be greater than that of females throughout life, so that by age 85 and over, the sex ratio is about 2 females : 1 male.

The sex of each birth appears to be random relative to previous births—that is, there do not seem to be tendencies for some families to have boys or for others to have girls. Many people are surprised by this fact, for they know of one or more large families consisting mostly of boys or mostly of girls. But the occasional family with children of predominantly one sex is expected simply by chance. When one occurs, its unusual sex distribution commands attention out of proportion to the actual numbers of such families. In short, families with unusual sex distributions are not more frequent than would be expected by chance.

#### Self-Assessment Questions

1. How can the human *X* and *Y* chromosomes pair during meiosis even though they are of different lengths and most of their genes are different?
2. What is the biological basis for the 1 : 1 ratio of males and females at conception in mammals?

## 16.2 INHERITANCE OF GENES IN THE X CHROMOSOME

Genes in the X chromosome are called **X-linked genes**. These genes have a unique pattern of inheritance first discovered by Thomas Hunt Morgan in 1910. Morgan's pioneering studies of genetics of the fruit fly *Drosophila melanogaster* helped bring Mendelian genetics into the modern era. The discovery of X-linked inheritance was not only important in itself, but it also provided the first experimental evidence that chromosomes contain genes.

### X-linked inheritance was discovered through studies of male fruit flies with white eyes.

Morgan's discovery of X-linked genes began when he noticed a white-eyed male in a bottle of fruit flies in which all the others had normal, or wild-type, red eyes. (The most common phenotype in a population is often called the **wild type**.) This was the first mutant he discovered, and finding it was a lucky break.

Morgan's initial crosses are outlined in **Fig. 16.3**. In the first generation, he crossed the mutant white-eyed male with a wild-type red-eyed female. All of the progeny ( $F_1$ ) fruit flies had wild-type red eyes, as you would expect from a cross with any recessive mutation. Morgan then carried out matings between brothers and sisters among the  $F_1$  generation, and he found that the mutant phenotype of white eyes reappeared among the progeny. This result, too, was expected.

However, there was a surprise: Morgan observed that the white-eye phenotype was associated with the sex of the fly. In the  $F_2$  generation, all the white-eyed fruit flies were male, and the white-eyed males appeared along with red-eyed males in a ratio of 1 : 1. No females with white eyes were observed; all the females had red eyes.

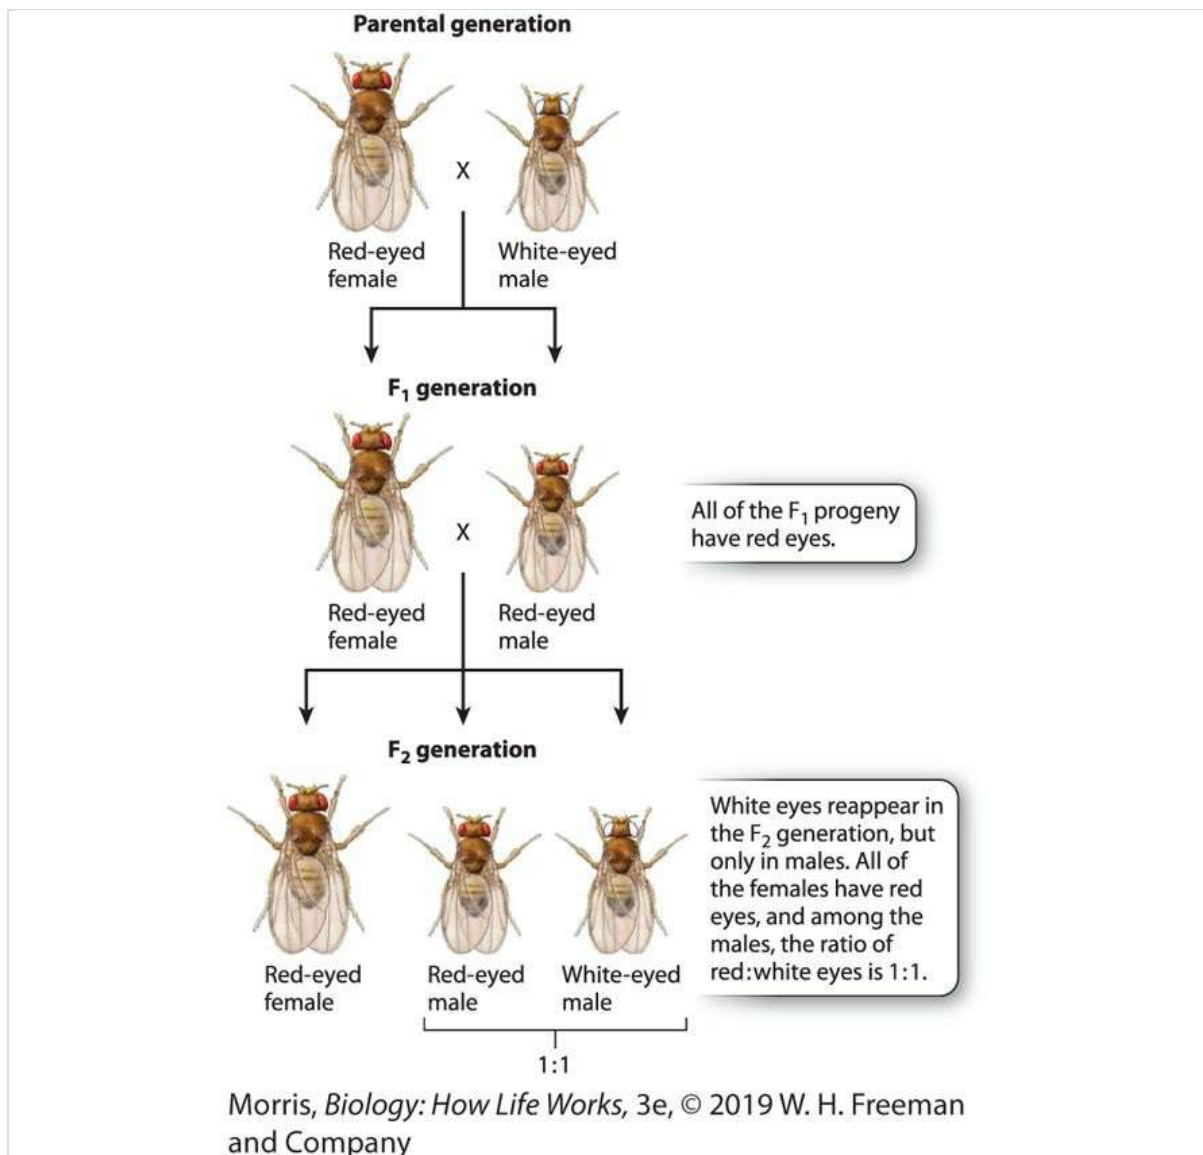

FIG. 16.3 Morgan's white-eyed fly. Morgan observed that the recessive white-eyed phenotype reappeared in the  $F_2$  generation, but in males only.

Genes in the X chromosome exhibit a

## crisscross inheritance pattern.

When Morgan did his crosses with the white-eyed male, the *X* chromosome had only recently been discovered by microscopic examination of the chromosomes in male and female grasshoppers. Morgan was the first to understand that the pattern of inheritance of the *X* chromosome would differ from that of the autosomes, and he proposed the hypothesis that the white-eyed phenotype was due to a mutation in a gene in the *X* chromosome. This hypothesis could explain the pattern of inheritance shown in [Fig. 16.3](#).

The key features of *X*-linked inheritance are shown in [Fig. 16.4](#). In *Drosophila*, as in humans, females are *XX* and males are *XY*. [Fig. 16.4a](#) shows an *XY* male in which the *X* chromosome contains a recessive mutation. Because the *Y* chromosome does not carry an allele of this gene, the recessive mutation will be reflected in the male's phenotype—in this case, white eyes.

a.

Most genes in the X chromosome have no counterparts in the Y chromosome. Therefore, a recessive mutation in an X-linked gene is expressed in males.

A male with an X-linked recessive trait will have heterozygous (carrier) daughters and normal sons.

b.

Among progeny from a heterozygous carrier female, half of the daughters are expected to be heterozygous carriers and half the sons are expected to be affected.

FIG. 16.4 X-linkage. (a) Cross between a homozygous nonmutant female and a male carrying an X-linked recessive allele (red). (b) Cross between a heterozygous female and a nonmutant male. X-linked recessive alleles are expressed in males because males have only one X chromosome.

The Punnett square in [Fig. 16.4a](#) explains why all the offspring had red eyes when Morgan crossed the white-eyed male with a red-eyed female in the parental generation. During meiosis in the male, the mutant X chromosome segregates from the Y chromosome, and each type of sperm, X or Y, combines with a normal X-bearing egg. The result is that the female progeny are heterozygous. They have only one copy of the mutant allele, and because the mutant allele is recessive, the heterozygous females do not express the mutant white-eye trait. The male progeny are also red-eyed because they receive their X chromosome from their wild-type red-eyed mother.

The Punnett square in [Fig. 16.4a](#) illustrates two important principles governing the inheritance of X-linked genes:

1. The phenotypes of the XX offspring indicate that a male transmits his X chromosome only to his daughters. In this case, the X chromosome transmitted by the male carries the white-eye mutation.
2. The phenotypes of the XY offspring indicate that a male inherits his X chromosome from his mother. In this case, the X chromosome transmitted by the mother carries the nonmutant allele of the gene.

These principles underlie a pattern often referred to as [crisscross](#)

**inheritance:** an *X* chromosome present in a male in one generation must be transmitted to a female in the next generation, and in the generation after that can be transmitted back to a male. Therefore, an *X* chromosome can crisscross, or alternate, between the sexes in successive generations.

The mating illustrated in [Fig. 16.4b](#) shows another important feature of *X*-linked inheritance, one that explains the results of Morgan's  $F_1$  cross. In this case, the mother is a heterozygous female. During meiosis, the mutant allele and the nonmutant allele undergo segregation. Half of the resulting eggs contain an *X* chromosome with the mutant allele, and half contain an *X* chromosome with the nonmutant allele. These combine at random with either *X*-bearing sperm or *Y*-bearing sperm. Among the female progeny in the next generation, half are heterozygous for the mutant allele and the other half are homozygous for the normal allele. Thus, none of the females exhibits the white-eye trait because the mutation is recessive. Among the male progeny, half receive the mutant allele and have white eyes, whereas the other half receive the nonmutant allele and have red eyes. The expected progeny from the cross in [Fig. 16.4b](#) therefore consist of all red-eyed females, and there is a 1 : 1 ratio of red-eyed to white-eyed males, which is what Morgan observed in the  $F_2$  generation of his crosses, as shown in [Fig. 16.3](#).

Knowing the patterns revealed by the Punnett squares, we can now assign genotypes to Morgan's original crosses ([Fig. 16.5](#)). In [Fig. 16.5](#), the white-eyed males that Morgan used in his parental generation crosses are given the genotype of  $w^- Y$ , and the red-eyed female has a

genotype of  $w^+w^+$ . The symbol “ $w^-$ ” stands for the recessive white-eye mutation in one  $X$  chromosome, and the symbol “ $w^+$ ” stands for the dominant nonmutant allele (red eyes) in the other  $X$  chromosome. The symbol “ $Y$ ” stands for the  $Y$  chromosome, and it is important to remember that the  $Y$  chromosome does not contain an allele of the white-eye gene.

FIG. 16.5 Genotypes of Morgan's white-eyed fruit fly crosses.

In the cross between a wild-type red-eyed female and a white-eyed male, illustrated in [Fig. 16.5a](#), the male offspring have red eyes because they receive their  $X$  chromosome from their mother. The female offspring from this cross receive one of their  $X$  chromosomes from their father, and hence they are heterozygous,  $w^+w^-$ . When the male and female F<sub>1</sub> progeny mate, their F<sub>2</sub> offspring consist of all red-

eyed females (half of which are heterozygous) and a 1 : 1 ratio of red-eyed to white-eyed males, exactly as Morgan had observed.

The hypothesis of *X*-linkage not only explained the original data, but it also predicted the results of other crosses. One important test is outlined in [Fig. 16.5b](#). Here, the parental cross is the same as that in [Fig. 16.5a](#), but instead of mating the  $F_1$  females to their brothers, they are mated to white-eyed males. The prediction is that there should be a 1 : 1 ratio of red-eyed females to white-eyed females as well as a 1 : 1 ratio of red-eyed males to white-eyed males. Again, these were the results observed. By the results of these crosses and others, Morgan demonstrated that the pattern of inheritance of the white-eye mutation parallels the pattern of inheritance of the *X* chromosome.

## *X*-linkage provided the first experimental evidence that genes are in chromosomes.

Morgan's original experiments indicated that the white-eye mutation showed a pattern of inheritance like that expected of the *X* chromosome. However, it was one of Morgan's students who showed experimentally that the white-eye mutation was actually a physical part of the *X* chromosome. Today, it seems obvious that genes are in chromosomes because we know that genes consist of DNA and that DNA in the nucleus is found in chromosomes. But in 1916, when Calvin B. Bridges, who had joined Morgan's laboratory as a freshman, was working on his PhD research under Morgan's direction, neither the chemical nature of the gene nor the chemical composition of

chromosomes was known.

In one set of experiments, Bridges crossed mutant white-eyed females with wild-type red-eyed males ([Fig. 16.6](#)). Usually, the progeny consisted of red-eyed females and white-eyed males ([Fig. 16.6a](#)). This is the result expected when the  $X$  chromosomes in the mother separate normally at anaphase I in meiosis because all the daughters receive a  $w^-$ -bearing  $X$  chromosome from their mother as well as a  $w^+$ -bearing  $X$  chromosome from their father, whereas all the sons receive a  $w^-$ -bearing  $X$  chromosome from their mother and a  $Y$  chromosome from their father.

**a. Normal chromosome separation**

**b. Nondisjunction**

FIG. 16.6 Nondisjunction as evidence that genes are present in chromosomes. (a) Normal chromosome separation yields expected progeny. (b) Nondisjunction yields exceptional progeny.

But Bridges noted a few rare exceptions among the progeny. He saw that about 1 offspring in 2000 from the cross was “exceptional”—either a female with white eyes or a male with red eyes. The exceptional females were fertile, and the exceptional males were sterile. To explain these exceptional progeny, Bridges proposed the hypothesis diagrammed in [Fig. 16.6b](#): the *X* chromosomes in a female occasionally fail to separate in anaphase I in meiosis, and both *X* chromosomes go to the same pole. Recall from [Chapter 11](#) that chromosomes sometimes fail to separate normally in meiosis, a process known as [nondisjunction](#). Nondisjunction of *X* chromosomes results in eggs containing either two *X* chromosomes or no *X* chromosome. [Figure 16.6b](#) shows the implications for eye color in the progeny if the hypothesis is correct. The exceptional white-eyed females would contain two *X* chromosomes plus a *Y* chromosome (genotype  $w^- / w^- / Y$ ), and the exceptional red-eyed males would contain a single *X* chromosome and no *Y* chromosome (genotype  $w^+$ ).

Bridges’s hypothesis for the exceptional progeny in [Fig. 16.6b](#) was bold, as it assumed that *Drosophila* males could develop in the absence of a *Y* chromosome (*XO* embryos yielding sterile males, where “*O*” indicates absence of a chromosome), and that females could develop in the presence of a *Y* chromosome (*XXY* embryos yielding fertile females). The hypothesis was accurate as well as bold. Microscopic examination of the chromosomes in the exceptional fruit flies

confirmed that the exceptional white-eyed females had  $XXY$  sex chromosomes and that the exceptional sterile red-eyed males had an  $X$  but no  $Y$ . Because fruit flies with three  $X$  chromosomes ( $XXX$ ) or no  $X$  chromosome ( $OY$ ) were never observed, Bridges concluded that embryos with these chromosomal constitutions are unable to survive. Bridges also conducted crosses that showed that nondisjunction can take place in males as well as in females. From the phenotypes of these exceptional fruit flies and their chromosome constitutions, Bridges concluded that the white-eye gene (and by implication any other  $X$ -linked gene) is physically present in the  $X$  chromosome.

Bridges's demonstration that genes are present in chromosomes was also the first experimental evidence of nondisjunction. *Drosophila* differ from humans in that the  $Y$  chromosome is necessary for male fertility but not for male development. As we will see later in this chapter, a gene in the  $Y$  chromosome itself is the trigger for male development in humans and other mammals, and so for these organisms, the  $Y$  chromosome is needed both for male development and male fertility. Nondisjunction occasionally takes place in meiosis in humans as well as in fruit flies. When nondisjunction takes place in the human sex chromosomes, it results in chromosomal constitutions such as  $47, XXY$  and  $47, XYY$  males as well as  $47, XXX$  and  $45, X$  females ([Chapter 11](#)). Nondisjunction of autosomes can also occur, resulting in fetuses that have extra copies or missing copies of entire chromosomes.

## Genes in the $X$ chromosome show characteristic patterns in human

## pedigrees.

The features of X-linked inheritance can be seen in human pedigrees for traits caused by an X-linked recessive mutation. These are illustrated in [Fig. 16.7](#) for red–green color blindness, a condition that affects about 1 in 20 males. An individual with red–green color blindness will have difficulty seeing the number in the colored dots in [Fig. 16.7](#).

The key features of the inheritance of traits due to rare X-linked recessive alleles, which are noted in the pedigree, are listed here:

1. Affected individuals are usually males because males need only one copy of the mutant gene to be affected, whereas females need two copies to be affected.
2. Affected males have unaffected sons because males transmit their X chromosome only to their daughters.
3. A female whose father is affected can have affected sons because such a female must be a heterozygous carrier of the recessive mutant allele.

An additional feature worth mentioning is that the sisters of an affected male each have a 50% chance of being a heterozygous carrier because when a brother is affected the mother must be heterozygous for the recessive allele.

A pedigree for one of the most famous examples of human X-linked inheritance is shown in [Fig. 16.8](#). The trait is a form of [hemophilia](#), which results from a recessive mutation in a gene encoding a protein necessary for blood clotting. Affected individuals bleed excessively from even minor cuts and bruises, and internal bleeding can cause excruciating pain. Affecting about 1 in 7000 males, hemophilia is famous because of its presence in many members of European royalty descended from Queen Victoria of England (1819–1901), whose pedigree later revealed her to be a heterozygous carrier of the gene. By the marriages of her carrier granddaughters, the gene was introduced into the royal houses of Germany, Russia, and Spain. The mutant allele is not present in the present royal family of Britain because this family descends from King Edward VII, one of Victoria's four sons, who was not himself affected and therefore passed only a normal X chromosome

to his descendants.

The source of Queen Victoria's hemophilia mutation is not known. None of her ancestors is reported as having a bleeding disorder. Quite possibly the mutation was present for a few generations before Victoria was born but remained hidden because it was passed from heterozygous female to heterozygous female.

### Self-Assessment Questions

- For a recessive X-linked mutation, such as color blindness, what is the pattern of inheritance from an affected male through his daughters into her children?
- Is it possible for an unaffected female to have female offspring with red-green color blindness?

---

## 16.3 GENETIC LINKAGE

Mendel was fortunate not only because peas do not possess sex chromosomes, but also because the genes that influenced the traits he studied, such as round/wrinkled and yellow/green seeds, are on separate chromosomes or far apart on the same chromosome. What happens when genes are close to each other in the same chromosome? We explore the answer to this question in this section.

### Nearby genes in the same chromosome show linkage.

Genes that are sufficiently close together in the same chromosome are said to be **linked**. That is, they tend to be transmitted together in inheritance and do not assort independently of each other as Mendel observed. Note that “linked genes” refers to two genes that are close together in the same chromosome, which may be an autosome or sex chromosome. This is not to be confused with an “X-linked gene,” which is one that is present anywhere in the X chromosome.

Linkage was discovered in *Drosophila* by Alfred H. Sturtevant, another of Morgan’s students. Once again, genes in the X chromosome played a key role in the discovery because the phenotypes of the male offspring of a female reveal the female’s genotype for X-linked genes. An example is shown in **Fig. 16.9**. Sturtevant worked with male fruit flies that have an X chromosome carrying two recessive mutations. One is in the *white* gene (*w*) discussed earlier, which when nonmutant (*w*<sup>+</sup>) results in fruit flies with red eyes and when mutant (*w*<sup>-</sup>) results in fruit flies with white eyes. The other recessive mutation is in a gene

called *crossveinless* (*cv*), which when nonmutant (*cv*<sup>+</sup>) results in fruit flies with tiny crossveins in the wings and when mutant (*cv*<sup>-</sup>) results in the absence of these crossveins.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 16.9 Linkage of the *white* (*w*) and *crossveinless* (*cv*) genes in the *X* chromosome. Genes are written according to their order along the chromosome, with a horizontal line between homologous chromosomes, in this case the *X* and *Y*. Crossveins are shown in red for clarity.

Sturtevant crossed this doubly mutant male with a female carrying the nonmutant forms of the genes ( $w^+$  and  $cv^+$ ) in both *X* chromosomes. He saw that the offspring consist of phenotypically wild-type females that are heterozygous for both genes, and phenotypically wild-type males. When these are crossed with each other, the female  $F_2$  progeny do not tell us anything because they are all wild type; each female receives the  $w^+ cv^+$  *X* chromosome from her father and therefore has red eyes and normal crossveins. In the male  $F_2$  progeny, however, the situation is different: each male progeny receives its *X* chromosome from the mother and its *Y* chromosome from the father, and so the phenotype of each male immediately reveals the genetic constitution of the *X* chromosome that the male inherited from the mother.

As shown in [Fig. 16.9](#), the male  $F_2$  progeny consist of four types:

| Genotype of $F_2$ Progeny                       | Number of Fruit Flies |
|-------------------------------------------------|-----------------------|
| $w^+ cv^+ / Y$ (red eyes, normal crossveins)    | 357                   |
| $w^- cv^- / Y$ (white eyes, missing crossveins) | 341                   |
| $w^+ cv^- / Y$ (red eyes, missing crossveins)   | 52                    |
| $w^- cv^+ / Y$ (white eyes, normal crossveins)  | 45                    |

Although all four possible classes of maternal gametes are observed in the male progeny, they do not appear in the ratio 1 : 1 : 1 : 1 expected when gametes contain two independently assorting genes ([Chapter 15](#)). The lack of independent assortment means that the genes show linkage.

The male progeny fall into two groups. One group, represented by larger numbers of progeny, derives from maternal gametes containing either  $w^+ cv^+$  or  $w^- cv^-$ . These are called **nonrecombinants** because the alleles are present in the same combination as that in the parent. The other group of male progeny consists of  $w^+ cv^-$  and  $w^- cv^+$  combinations of alleles. These are called **recombinants**, and they result from a crossover, the physical exchange of parts of homologous chromosomes, which takes place in prophase I of meiosis ([Chapter 11](#)).

Crossing over is a key process in meiosis ([Chapter 11](#)). Most chromosomes have one or more crossovers that form between the homologous chromosomes as they pair and undergo meiosis. Human females average about 2.75 crossovers per chromosome pair, and human males average about 2.50 crossovers per chromosome pair. As noted earlier for the *X* and *Y* chromosomes, crossovers between homologous chromosomes are important mechanically because they help hold the homologs together so they can align properly at metaphase I and segregate to opposite poles at anaphase I.

**Fig. 16.10** shows how chromosomes with recombined alleles arise from crossing over between genes, using the hypothetical genes *A* and *B*. In a cell undergoing meiosis in which a crossover takes place

between the genes, the allele combinations are broken up in the chromatids involved in the exchange, and the resulting gametes are  $AB$ ,  $Ab$ ,  $aB$ , and  $ab$  ([Fig. 16.10a](#)).

FIG. 16.10 Linkage and recombination. (a) Crossing over between genes results in recombination between the alleles of the genes. (b) When crossing over occurs outside the interval between genes, there is no recombination between the alleles of the genes.

Note that crossing over does not result only in recombinant chromosomes. [Fig. 16.10a](#) shows that, even when a crossover occurs in the interval between the genes, two of the resulting chromosomes contain the nonrecombinant configuration of alleles. These nonrecombinant configurations occur because crossing over occurs at the four-strand stage of meiosis (when each homologous chromosome is a pair of sister chromatids), but only two of the four strands (one sister chromatid from each homologous chromosome) are included in any crossover.

[Fig. 16.10b](#) shows a second way in which nonrecombinant chromosomes originate. When two genes are close together in a chromosome, a crossover may occur not in the interval between the genes but at some other location along the chromosome. In this example, the crossover occurs in the region between gene *A* and the centromere, and therefore the combination of alleles *A* and *B* remains intact in one pair of chromatids and the combination of alleles *a* and *b* remains intact in the homologous chromatids. The resulting gametes are equally likely to have either *AB* or *ab*, both of which are nonrecombinant.

Nonrecombinant chromosomes can also be the result of two crossover events occurring between two genes, in which the effects of the first crossover (creating recombinants) is reversed by a second crossover (re-creating nonrecombinants).

## The frequency of recombination is a measure of the genetic distance between linked genes.

When two genes are on separate chromosomes, a ratio of 1 : 1 : 1 : 1 is expected for the nonrecombinant (parental) and recombinant (nonparental) gametic types, as described by the principle of independent assortment ([Chapter 15](#)). For two genes present in the same chromosome, we can consider two extreme situations. If they are located very far apart from each other, one or more crossovers will almost certainly occur between them, and there will be a 1 : 1 : 1 : 1 ratio of nonrecombinant and recombinant gametes (as shown for the

case of a single crossover in [Fig. 16.10a](#)). At the other extreme, if two genes are so close together that crossing over never takes place between them, we would expect only nonrecombinant chromosomes.

What happens in between these extremes? In these cases, in some cells undergoing meiosis, no crossover takes place between the genes, in which case all the resulting chromosomes are nonrecombinant ([Fig. 16.10b](#)); in other cells undergoing meiosis, a crossover occurs between the genes, in which case half the resulting chromosomes are nonrecombinant and half are recombinant ([Fig. 16.10a](#)).

The actual frequency of recombinants depends on the distance between the genes. The distance between the genes is important because whether or not a crossover occurs between the genes is a matter of chance, and the closer the genes are along the chromosome, the less likely it is that a crossover will take place in the interval between them. Because the formation of recombinant chromosomes requires at least one crossover between the genes, genes that are close together (more tightly linked) show less recombination than genes that are far apart. In fact, the proportion of recombinant chromosomes observed among the total, which is called the [frequency of recombination](#), is a measure of genetic distance between the genes along the chromosome.

In the example with the genes *w* and *cv*, the total number of chromosomes observed among the progeny is  $357 + 341 + 52 + 45 = 795$ , and the number of recombinant chromosomes ( $w^+ cv^- / Y$  and  $w^- cv^+ / Y$ ) is  $52 + 45 = 97$ . The frequency of recombination between *w*

and  $cv$  is therefore  $97/795 = 0.122$ , or 12.2%, and this serves as a measure of the genetic distance between the genes. In studies of genetic linkage, the distance between genes is not measured directly by physical distance between them, but rather by the frequency of recombination.

The frequency of recombination between any two genes on the same chromosome ranges from 0% (when genes are so close together that crossing over never takes place between them) to 50% (when the genes are so far apart that a crossover between the genes almost always takes place). Genes that are linked have a recombination frequency somewhere between 0% and 50%. The maximum frequency of recombination is 50% provided that the non-sister chromatids involved in any crossover are chosen at random. A frequency of recombination of 50% yields the same ratio of gametic types as observed with independent assortment, which means that genes that are far enough apart in the same chromosome show independent assortment.

Recombination plays an important role in creating new combinations of alleles in each generation and in ensuring the genetic uniqueness of each individual. If there were no recombination (that is, if all the alleles in each chromosome were completely linked), any individual human would be able to produce only  $2^{23} = 8.4$  million types of reproductive cells. Although this is a large number, the average number of sperm per ejaculate is much larger—approximately 350 million. Because recombination does occur, and because the crossovers resulting in recombination can occur at any of thousands of different positions in the genome, each of the 350 million sperm is

virtually certain to carry a different combination of alleles.

## Genetic mapping assigns a location to each gene along a chromosome.

With the exception of a few regions, such as the area near the centromere, the likelihood of a crossover occurring somewhere between two points on a chromosome is approximately proportional to the length of the interval between the points. Therefore, the frequency of recombination can be used as a measure of the physical distance between genes. These distances are used in the construction of a **genetic map**, which is a diagram showing the relative position of genes along a chromosome. The maps are drawn using a scale in which one unit of distance (called a **map unit**) is the distance between genes resulting in 1% recombination. Thus, in a *Drosophila* genetic map containing the genes *w* and *cv* that have a recombination frequency of 12.2%, the distance between the genes is 12.2 map units.

Genetic maps are built up step by step as new genes are discovered that are genetically linked, as shown in **Fig. 16.11**. Across distances that are less than about 15 map units, the map distances are approximately additive, which means that the distances between adjacent genes can be added to get the distance between the genes at the ends. For example, in **Fig. 16.11**, there are two genes between *w* and *cv*. The map distance between *w* and the next gene, *ec*, is 4.0, the distance between *ec* and the next gene, *rb*, is 2.0, and the distance between *rb* and *cv* is 6.2. The map distance between *w* and *cv* is therefore  $4.0 + 2.0 + 6.2 = 12.2$  map units, and hence the expected frequency of recombination between these genes is 12.2%, which is the

value observed.

However, for two genes that are farther apart than about 15 map units, the observed recombination frequency is somewhat smaller than the sum of the map distances between the genes. The reason is that, with greater distances, two or more crossovers between the genes may occur in the same chromosome, and thus an exchange produced by one crossover may be reversed by another crossover farther along the way.

#### HOW DO WE KNOW?

### FIG. 16.11

## Can recombination be used to construct a genetic map of a chromosome?

#### BACKGROUND

In 1910, American geneticist Thomas Hunt Morgan discovered *X*-linkage by studying the white-eye mutation in *Drosophila*. Soon other *X*-linked mutations were found. Alfred H. Sturtevant, Morgan's student, decided to test whether mutant genes in the same *X* chromosome were inherited together, that is, linked. He found that genes in the *X* chromosome were linked, but not completely, and that different pairs of genes showed great differences in their linkage. Some genes showed almost no recombination, whereas others underwent so much recombination that they showed independent assortment.

#### HYPOTHESIS

Sturtevant hypothesized that recombination was due to crossing over between the genes, and that genes farther apart in the chromosome would show more recombination.

#### EXPERIMENT

Taking this idea a step further, Sturtevant reasoned that if one knew the frequency of recombination between genes *a* and *b*, between *b* and *c*, and between *a* and *c*, then one should be able to deduce the order of these three genes along the chromosome. The logic is that the two genes showing the highest frequency of recombination are farthest apart, and the third gene is in the middle. He also predicted that, if the order of genes were known to be *a–b–c* and if the genes were close enough, the frequency of recombination between *a* and *c* should equal the sum of the frequency of recombination between *a* and *b* and the frequency of recombination between *b* and *c*.

## RESULTS

Sturtevant studied the frequencies of recombination between many pairs of genes along the X chromosome, including some of those in the illustration shown here.

## CONCLUSION

The results supported Sturtevant's hypothesis and showed that genes could be arranged in the form of a genetic map, depicting their linear order along the chromosome, with the distance between any pair of genes proportional to the frequency of recombination between them. Across sufficiently short regions, the frequencies of recombination are additive.

#### FOLLOW-UP WORK

Genetic mapping remains a cornerstone of genetic analysis, allowing researchers to determine which chromosome contains a mutant gene and where along the chromosome the gene is located. The method helped to identify the genes responsible for many single-gene inherited disorders, including Huntington's disease, cystic fibrosis, and muscular dystrophy.

SOURCE Sturtevant, A. H. 1913. "The Linear Arrangement of Six Sex-Linked Factors in *Drosophila*, as Shown by Their Mode of Association." *Journal of Experimental Zoology* 14:43–59.

## Genetic risk factors for disease can be localized by genetic mapping.

The discovery of abundant genetic variation in DNA sequences in human populations, such as single-nucleotide polymorphisms ([Chapter 14](#)), made it possible to study genetic linkage in the human genome. At first, the focus was on finding mutations that cause disease, such as the mutation that causes cystic fibrosis. The method was to study large families extending over three or more generations in which the disease was present and then to identify the genotypes of each of the individuals for thousands of genetic markers (previously discovered DNA polymorphisms) throughout the genome. The goal was to find genetic markers that showed a statistical association with the disease gene, which would indicate genetic linkage and reveal the approximate location of the disease gene along the chromosome.

[Fig. 16.12](#) illustrates the underlying concept. It assumes 100 chromosomes observed among different individuals in a pedigree, of which 50 carry a mutant allele of a gene and 50 carry a nonmutant

allele. These chromosomes are tested for a marker of known location, in this case a single-nucleotide polymorphism (SNP) in which one of the nucleotide pairs in the DNA is a G—C base pair in some chromosomes and A—T in others. In [Fig. 16.12a](#), there is clearly an association between the disease gene and the SNP. Almost all of the chromosomes that carry the mutant allele show the G—C nucleotide pair, whereas almost all of the chromosomes that carry the nonmutant allele show the A—T nucleotide pair. The two chromosomes in which the mutant and nonmutant genes are associated with the other SNPs can be attributed to recombination. Associations between disease genes and SNPs arise because of ancestry. When a new mutation takes place, it occurs in a single chromosome surrounded by a particular combination of SNP alleles. If the new mutation increases in frequency and establishes itself in the population, the particular combination of SNP alleles is carried along. The tighter the linkage between the mutation and the surrounding SNP alleles, the longer the association persists.

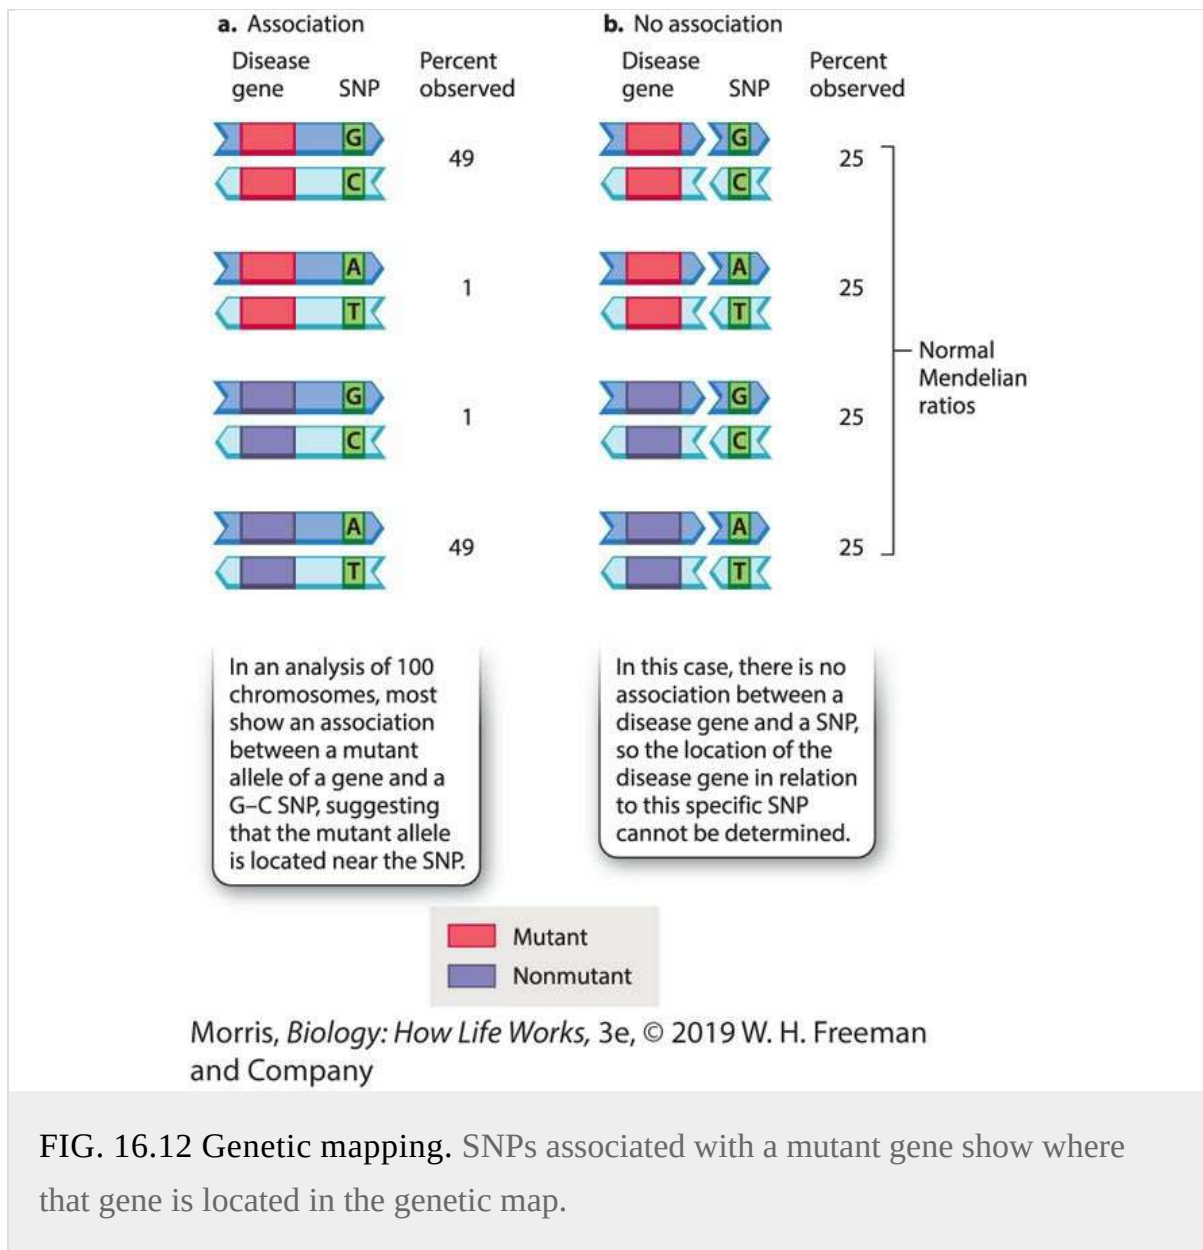

FIG. 16.12 Genetic mapping. SNPs associated with a mutant gene show where that gene is located in the genetic map.

The association in [Fig. 16.12a](#) may be contrasted with the pattern in [Fig. 16.12b](#), in which there is no association. In [Fig. 16.12b](#), each of the alleles of the disease gene is equally likely to carry either form of the SNP. The failure to find an association means that the SNP is not closely linked to the disease gene, and may in fact be in a different chromosome. In actual studies, an association is almost never observed, but the lucky find of an association helps identify the location of the disease gene in the genetic map. Using such association

methods, hundreds of important disease genes have been located by genetic mapping. Once the location of the disease gene is known, the identity and normal function of the gene can be determined.

#### Self-Assessment Questions

5. Why don't linked genes exhibit independent assortment?
6. Why is the upper limit of recombination 50% rather than 100%?
7. For two genes that show independent assortment, what is the frequency of recombination?
8. How can recombination frequency be used to build a genetic map?

## 16.4 INHERITANCE OF GENES IN THE Y CHROMOSOME

Like the *X* chromosome, the *Y* chromosome exhibits a particular pattern of inheritance because of its association with the male sex. In humans and other mammals, all embryos initially develop immature internal sexual structures of both females and males. *SRY*, a gene in the *Y* chromosome, encodes a protein that is the trigger for male development. (“*SRY*” stands for “sex-determining region in the *Y* chromosome.”) In the presence of *SRY*, male structures complete their development and female structures degenerate. In the absence of *SRY*, male embryonic structures degenerate and female structures complete their development. The *SRY* gene is therefore the male-determining gene in humans and other mammals. Because they are linked to *SRY*, most genes in the *Y* chromosome show a distinctive pattern of inheritance in pedigrees, different from the patterns of autosomal genes Mendel observed in his pea plants, in that they are transmitted only from father to son.

### Y-linked genes are transmitted from father to son.

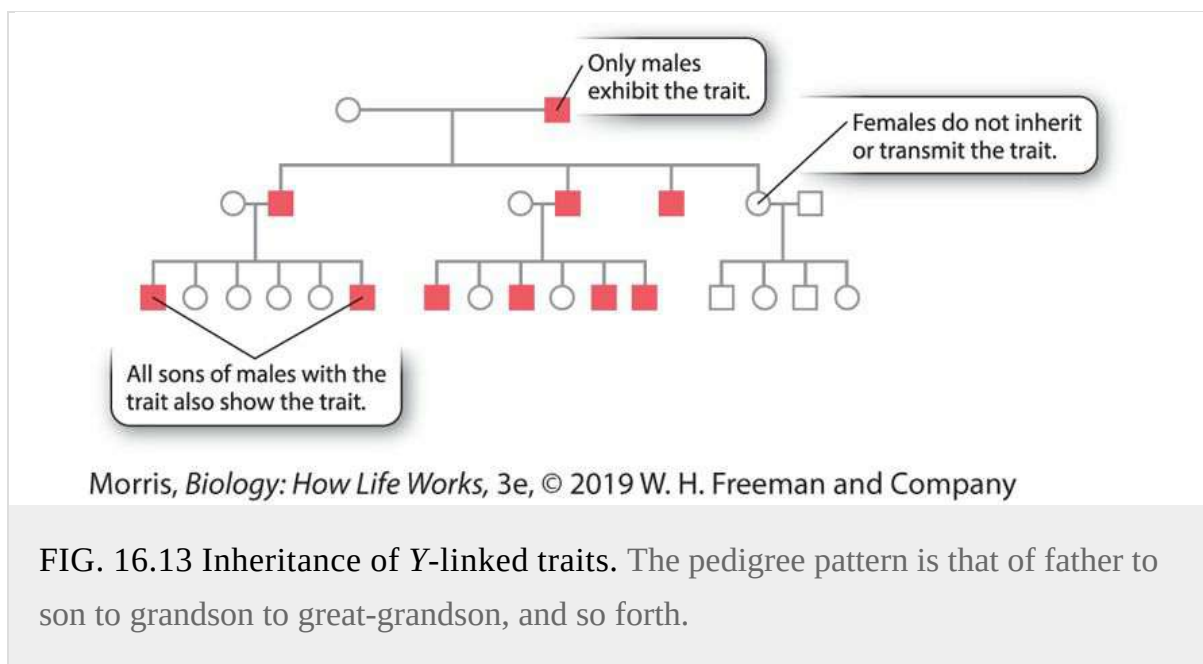

Genes that are present in the unique region of the *Y* chromosome (the part that cannot cross over with the *X*) are known as **Y-linked genes**. In addition to the *SRY* male-determining gene, the small number of Y-linked genes include several in which mutations are associated with impaired fertility and low sperm count.

The pedigree characteristics of Y-linked inheritance are striking

(Fig. 16.13):

1. Only males are affected with the trait.
2. Females never inherit or transmit the trait, regardless of how many affected male relatives they have.
3. All sons of affected males are also affected.

Because the Y chromosome is always transmitted from father to son (and never transmitted to daughters), a trait determined by a Y-linked gene will occur in fathers, sons, grandsons, and so forth. Traits resulting from Y-linked genes cannot be present in females nor can they be transmitted by females. However, other than maleness itself and some types of impaired fertility, no physical traits are known that follow a strict Y-linked pattern of inheritance. This observation emphasizes the extremely low density of functional genes in the Y chromosome.

T

## How can the *Y* chromosome be used to trace ancestry?

Your personal genome not only can tell you about your genetic risk factors for disease, but it also contains important information about your genetic ancestry. For example, your male ancestors can be traced through your *Y* chromosome. The regions at the tips in which the *X* and *Y* chromosomes share homology is only about 6% of the entire length of the *Y* chromosome. This means that 94% of the *Y* chromosome consists of sequences that are completely linked with one another because that portion of the chromosome does not pair with another chromosome and does not undergo crossing over.

Because of this complete linkage, each hereditary lineage of *Y* chromosomes is separate from every other lineage. As mutations occur along the *Y* chromosome, they are completely linked to any past mutations that may be present and also completely linked to any future mutations that may take place. The mutations therefore accumulate, allowing the evolutionary history of a set of sequences to be reconstructed.

**Fig. 16.14** shows an evolutionary tree based on the accumulation of mutations at a set of nucleotide sites along the *Y* chromosome. Each unique combination of nucleotides constitutes a *Y*-chromosome **haplotype**, or haploid genotype. In the figure, the most ancient *Y*

chromosomes are at the top, and the accumulation of new mutations as the generations proceed results in the successive creation of new haplotypes. Each Y-chromosome lineage may leave some nonmutant descendants as well as some mutant descendants, and hence any or all of the sequences shown may coexist in a present-day population.

In human history, the mutations creating new Y-chromosome haplotypes were occurring at the same time as populations were migrating and founding new settlements across the globe, and so each geographically distinct population came to have a somewhat different set of Y-chromosome haplotypes. The differences among populations are offset to some extent by migration among populations, which mixes the geographical locations of various haplotypes. Nevertheless,

the fact that the mutations accumulate through time and are completely linked allows the evolutionary history of the haplotypes to be reconstructed. It also enables Y chromosomes to be traced to their likely ethnic origin.

The worldwide distribution of real Y-chromosome lineages among human populations is shown in [Fig. 16.15](#). The different colors in the pie charts represent different haplotypes. Neighboring populations tend to have more closely related Y chromosomes than more distant populations, as seen in the similarly colored sectors of neighboring pie charts. Four major clusters of Y-chromosome lineages can be recognized in [Fig. 16.15](#). One is concentrated in Africa, another in Southeast Asia and Australia, a third in Europe and central and western Asia, and the fourth in North and South America. These clusters correspond roughly with the spread of human settlements around the globe inferred from archaeological evidence.

FIG. 16.15 Geographical distribution of Y-chromosome haplotypes among native populations. The evolutionary trees of Y-chromosome haplotypes reflect the origin and movement of different Y chromosomes over time. *Data from M. A.*

*Jobling and C. Tyler-Smith, 2003, "The Human Y Chromosome: An Evolutionary Marker Comes of Age," Nature Reviews Genetics 4:598–612.*

The implication of [Fig. 16.15](#) is that the haplotype of your Y chromosome (if you have a Y chromosome) contains genetic information about its origin. And you can learn what this information is from genetic testing companies that sell direct-to-consumer (DTC) services. Their tests are not regarded as medical devices and so are unregulated, and quality control is sometimes uncertain. Nevertheless, you can send saliva or other biological samples to a DTC provider, which will (for a fee) test your Y chromosome and send you a report that details its possible origin. Of course, because of recombination and independent assortment of genes in other chromosomes, the ethnic origin of your Y chromosome may have little or nothing to do with the ethnic origins of genes in any of your other chromosomes.

#### Self-Assessment Questions

9. What is the pattern of inheritance expected from a Y-linked gene in a human pedigree?
10. How can Y-chromosome data can be used to trace ancestry?

# 16.5 INHERITANCE OF MITOCHONDRIAL AND CHLOROPLAST DNA

Sex chromosomes and linked genes are not the only genes that are inherited in ways that are unlike the patterns of inheritance that Mendel observed in peas. Genes in mitochondria and chloroplasts also show distinct inheritance patterns. Mitochondria and chloroplasts are organelles of eukaryotic cells originally acquired by the engulfing of prokaryotic cells ([Chapter 5](#)). Mitochondria generate ATP that cells use for their chemical energy. Chloroplasts are found only in plant cells and eukaryotic algae. These organelles carry out photosynthesis, producing sugars that are essential for growth ([Chapter 8](#)).

Mitochondria and chloroplasts have their own genomes that contain genes for many of the enzymes that carry out the organelles' functions. Genes present in these genomes move with the organelle during cell division, independent of the segregation of chromosomes in the nucleus.

## Mitochondrial and chloroplast genomes often show uniparental inheritance.

During sexual reproduction, organelles do not show the regular, highly choreographed movements that chromosomes undergo during cell division. Organelles are partitioned to the gametes along with other cytoplasmic components, and therefore their mode of inheritance in

different species depends on how the gametes are formed, how much cytoplasm is included in the gametes, and the fate of the cytoplasm in each parental gamete after fertilization.

Considering the great diversity in the details of reproduction in different groups of organisms, it is not surprising that there is a diversity of types of inheritance of cytoplasmic organelles. The three most important types are:

- **Maternal inheritance**, in which the organelles in the offspring cells derive from those in the mother.
- **Paternal inheritance**, in which the organelles in the offspring cells derive from those in the father.
- **Biparental inheritance**, in which the organelles in the offspring cells derive from those in both parents.

In most organisms, either maternal inheritance or paternal inheritance predominates, but sometimes there is variation from one offspring to the next. For example, transmission of chloroplasts ranges from strictly paternal in the giant redwood *Sequoia*, to strictly maternal in the sunflower *Helianthus*, to either maternal or paternal (or less frequently biparental) in the fern *Scolopendrium*, to mostly maternal but sometimes paternal or biparental in the snapdragon *Antirrhinum*.

There is likewise great diversity among organisms in the inheritance of mitochondrial DNA. Most animals show maternal transmission of mitochondria, as would be expected from their large, cytoplasm-rich eggs and the small, cytoplasm-poor sperm. Among other organisms,

there is again much variation, including maternal transmission of mitochondria in flowering plants and paternal transmission in the green alga *Chlamydomonas*.

## Maternal inheritance is characteristic of mitochondrial diseases.

In humans and other mammals, mitochondria normally show strictly maternal inheritance—the mitochondria in the offspring cells derive from those in the mother. [Fig. 16.16](#) shows the characteristic pedigree patterns of a trait encoded by a mitochondrial genome transmitted through maternal inheritance:

1. Both males and females can show the trait.
2. All offspring from an affected female show the trait.
3. Males do not transmit the trait to their offspring.

The pedigree in [Fig. 16.16](#) follows a mitochondrial disease known as MERRF syndrome (the acronym stands for “myoclonic epilepsy with ragged red fibers”). As its name suggests, the syndrome is characterized by epilepsy, a neurological disease characterized by seizures, as well as by the accumulation of abnormal mitochondria in muscle fibers. This extremely rare disease is associated with a single point mutation in a mitochondrial gene involved in protein synthesis that affects oxidative phosphorylation ([Chapter 7](#)).

Inherited mitochondrial diseases are often associated with muscle weakness reflecting deficient production of ATP. The red patches in the microscopic image result from clumps of defective mitochondria in muscle fibers observed in one form of epilepsy that results from a mutation in mitochondrial DNA.

 Source: Courtesy of Dr. Kurenai Tanji, Columbia University Medical Center, New York, NY.

FIG. 16.16 Maternal inheritance. Human mitochondrial DNA is transmitted from a mother to all of her offspring.

More than 40 different diseases show these pedigree characteristics. They all result from mutations in the mitochondrial DNA, but the tissues and organs affected as well as the severity differ from one to the next. All of the mutations affect energy production in one way or another. In some cases, disease results directly from lack of adequate amounts of ATP, in other cases, from intermediates in energy production that are toxic to the cell or that damage the mitochondrial DNA.

## CASE 3 YOUR PERSONAL GENOME: YOU, FROM A TO

T

### How can mitochondrial DNA be used to trace ancestry?

Sequencing of mitochondrial DNA reveals mitochondrial haplotypes analogous to those in the *Y* chromosome. As in the *Y* chromosome, mutations in mitochondrial DNA accumulate through time, and each mitochondrial haplotype remains intact through successive generations because two mitochondrial genomes in an individual never come into contact and therefore cannot recombine. This means that mitochondrial DNA can be used to trace ancestry and population history, much as described previously for the *Y* chromosome. The mitochondrial DNA is actually more informative than *Y*-chromosomal DNA: it shows substantially more genetic variation, so its ancestry can be tracked on a finer scale.

The use of mitochondrial DNA to trace human origins and migration is discussed in greater detail in [Chapter 23](#). As with the *Y* chromosome, your personal mitochondrial genome includes information about its origin. If you want to learn about your mitochondrial DNA, you can send a tissue sample to any of a number of direct-to-consumer genotyping services that will, for a fee, analyze the DNA and provide you with a report.

Self-Assessment Questions

11. A man affected with a mitochondrial disease mates with a woman who does not have a mitochondrial disease. What is the probability that their offspring will be affected?
  12. How can mitochondrial DNA data be used to trace ancestry?
-

## CORE CONCEPTS SUMMARY

**16.1 THE X AND Y CHROMOSOMES:** Many organisms have a distinctive pair of chromosomes that differ between the sexes and show different patterns of inheritance from other chromosomes.

In humans and other mammals, *XX* individuals are female and *XY* individuals are male. [page 344](#)

The human *X* and *Y* chromosomes are different lengths and contain different genes, except for small regions of homology that allow the two chromosomes to pair in meiosis. [page 344](#)

Segregation of the *X* and *Y* chromosomes during male meiosis results in half of the sperm receiving an *X* chromosome and half a *Y* chromosome so that random union of gametes predicts a 1 : 1 female : male sex ratio at the time of fertilization. [page 344](#)

**16.2 INHERITANCE OF GENES IN THE X CHROMOSOME:** *X*-linked genes show a crisscross inheritance pattern.

Thomas Hunt Morgan studied a mutation in the fruit fly *Drosophila melanogaster* that resulted in fruit flies with white eyes rather than wild-type red eyes. In this species, as in mammals, females are *XX* and males are *XY*. [page 345](#)

In a cross of a normal red-eyed female with a mutant white-eyed male, all of the male and female progeny had red eyes. When brothers and sisters of this cross were mated with each other, all of the females had red eyes, but males were red-eyed and white-eyed in a 1 : 1 ratio. [page 345](#)

This pattern of inheritance is observed because the gene Morgan studied is located in the *X* chromosome. The nonmutant  $w^+$  allele is dominant to the mutant  $w^-$  allele, and the gene is present only in the *X* chromosome and not in the *Y* chromosome. [page 346](#)

*X*-linked genes show a crisscross inheritance pattern, in which the *X* chromosome with the mutant gene that is present in males in one generation is present in females in the next generation. [page 347](#)

Calvin Bridges observed rare fruit flies that did not follow the usual pattern for *X*-linked inheritance and inferred that these exceptional fruit flies resulted from nondisjunction, or failure of homologous chromosomes to segregate, in male or female meiosis. His observations provided evidence that genes are carried in chromosomes. [page 347](#)

In humans, *X*-linked inheritance shows a pattern in which affected individuals are almost always males, affected males have unaffected sons, and a female whose father is affected can have affected sons. [page 349](#)

**16.3 GENETIC LINKAGE:** Genes that are close together in the same chromosome tend to remain together in inheritance.

Genes that are close together in the same chromosome are linked and do not undergo independent assortment. [page 350](#)

Recombinant chromosomes result from crossing over between genes on the same chromosome and show a nonparental combination of alleles. [page 351](#)

Nonrecombinant chromosomes have the same configuration of alleles as one of the parental chromosomes. [page 351](#)

In genetic mapping, the observed proportion of recombinant chromosomes is the frequency of recombination and can be used as a measure of distance along a chromosome. A recombination frequency of 1% is 1 map unit. [page 351](#)

Gene linkage and mapping are used to identify the locations of disease genes in the human genome. [page 353](#)

#### **16.4 INHERITANCE OF GENES IN THE Y CHROMOSOME:**

Most Y-linked genes are passed from father to son.

In humans and other mammals, the Y chromosome contains a gene called *SRY* that results in male development. [page 355](#)

In Y-linked inheritance, only males are affected and all sons of an affected male are affected. Females are never affected and do not transmit the trait. [page 355](#)

Most Y-linked genes show complete linkage, which allows their evolutionary history to be traced. [page 356](#)

#### **16.5 INHERITANCE OF MITOCHONDRIAL AND**

**CHLOROPLAST DNA:** Mitochondria and chloroplast DNA follow their own inheritance pattern.

Mitochondria and chloroplasts have their own genomes, which reflect their evolutionary history as free-living prokaryotes. [page 357](#)

Mitochondria in humans and other mammals show maternal inheritance, in which individuals inherit their mitochondrial DNA from their mother. [page 358](#)

Because mitochondrial DNA does not undergo recombination and is maternally inherited, it can be used to trace human ancestry and migration. [page 358](#)

## CHAPTER 17 The Genetic and Environmental Basis of Complex Traits

Ryan McVay/Getty Images

---

## CORE CONCEPTS

**17.1 HEREDITY AND ENVIRONMENT:** Complex traits are those influenced both by the action of many genes and by environmental factors.

**17.2 RESEMBLANCE AMONG RELATIVES:** Genetic effects on complex traits are reflected in resemblance among relatives.

**17.3 TWIN STUDIES:** Twin studies help separate the effects of genotype and environment on variation in a trait.

**17.4 COMPLEX TRAITS IN HEALTH AND DISEASE:** Many common diseases and birth defects are affected by multiple genetic and environmental risk factors.

---

Biologists initially had a hard time accepting the principles of Mendelian inheritance because they seem so at odds with everyday observations. Common and easily observed traits such as height, weight, hair color, and skin color give no clear-cut phenotypic ratios such as 3 : 1 or 9 : 3 : 3 : 1 observed for simple Mendelian traits. The lack of these characteristic ratios raised serious doubt whether Mendel's principles are valid for common traits. Some biologists concluded that they apply only to seemingly trivial traits such as round and wrinkled seeds in peas.

At about the time that Mendel was studying inheritance in garden peas, the biologist Francis Galton, a friend and cousin of Charles Darwin, was studying common traits including human height. From studies of height and other common traits in parents and their offspring, Galton discovered general principles in the inheritance of

such traits. For example, parents who are tall tend to have offspring who are taller than average but not as tall as themselves. Galton's principles for the inheritance of common traits did not refer to genes, segregation, independent assortment, or other features of Mendelian inheritance, but they did describe Galton's observations. Genes—what Mendel called “hereditary factors”—were unnecessary in Galton's theory of inheritance, and many biologists thought that Galton's observations and Mendel's laws were incompatible.

This, it turned out, was not the case. The traits that Mendel studied are now called **single-gene traits** because each one is determined by variation at a single gene and the traits for the most part are not influenced by the environment. By focusing on single-gene traits, Mendel was able to infer underlying mechanisms of inheritance based on physical factors we now call genes. By contrast, **complex traits**, such as human height, are influenced by multiple genes as well as by the environment. As a result, their inheritance patterns are more difficult to follow and simple phenotypic ratios are not observed.

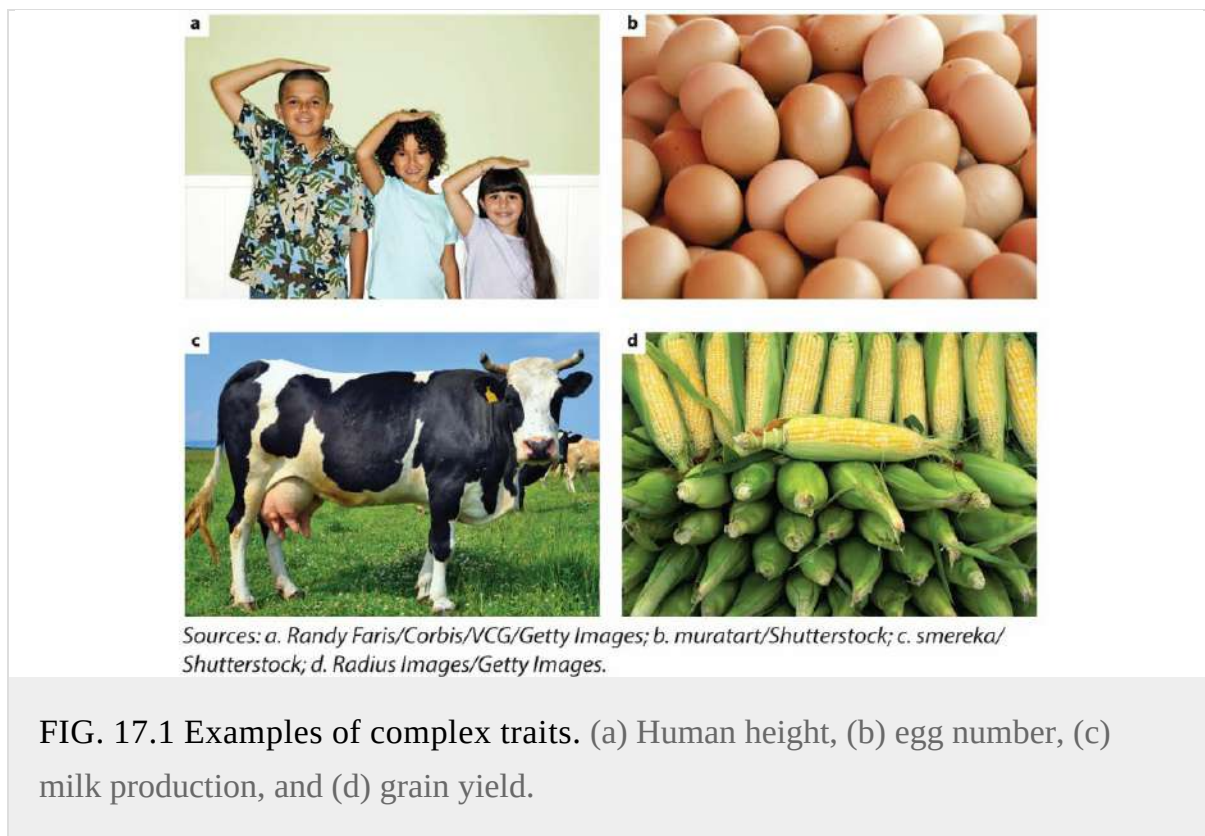

In many ways, complex traits are more important than single-gene Mendelian traits. One reason is their prevalence—complex traits are found in all organisms and include most of the traits we can see around us. By contrast, there are relatively few examples of common single-gene traits. Complex traits are also important in human health and disease. In the most common disorders—among them heart disease, diabetes, autism, and schizophrenia—single-gene Mendelian inheritance is seldom found. It is therefore important to understand the inheritance of complex traits and common disorders, which is the

subject of this chapter. We begin by describing some of the features of complex traits, and then show how these principles are not only compatible with, but are in fact predicted by, Mendelian inheritance. Finally, we describe how modern molecular genetics and genomics have allowed the identification of genes affecting complex traits.

# 17.1 HEREDITY AND ENVIRONMENT

Complex traits are important not only in humans, but in all organisms—including agricultural plants and animals. We will examine human height in some detail because it has been widely studied, but equally well-known complex traits are number of eggs laid by hens, milk production in dairy cows, and yield per acre of grain ([Fig. 17.1](#)).

Many common human diseases, including high blood pressure, obesity, diabetes, and depression, are complex traits ([Fig. 17.2](#)). High blood pressure, for example, affects about one-third of the U.S. population, and obesity another third. Type 2 diabetes affects around 8% of the U.S. population, and an estimated 15% will suffer at least one episode of severe depression in the course of a lifetime. Taken

together, about 200 million Americans—two-thirds of the entire population—suffer from one or more of these common disorders. None of these traits shows single-gene Mendelian inheritance.

FIG. 17.2 Examples of human diseases that are complex traits. (a) High blood pressure, (b) obesity, (c) diabetes, and (d) depression.

In many complex traits, the phenotype of an individual is determined by measurement: human height is measured in inches, milk yield by the gallon, grain yield by the bushel, egg production by the number of eggs, blood pressure by millimeters of mercury, and blood sugar by millimoles per liter. Because the phenotype of complex traits such as these is measured along a continuum with only small intervals between similar individuals, complex traits such as these are often called **quantitative traits**. By contrast, single-gene traits often appear in one of two or more different phenotypes, such as round versus wrinkled seeds, or green versus yellow seeds.

## Complex traits are affected by the environment.

Expression of complex traits is notoriously susceptible to lifestyle choices and other environmental factors. Inadequate nutrition is linked

to slow growth rate and short stature in adults. Salt intake is associated with an increased likelihood of high blood pressure and is therefore an **environmental risk factor** for this common disorder. An environmental risk factor is a characteristic in a person's surroundings that increases the likelihood of developing a particular disease. For example, a junk-food diet high in fat and carbohydrates is an environmental risk factor for obesity and diabetes.

Environmental effects are also important in agriculture. Farmers are well aware that adequate nutrition is essential to normal growth of chicks, lambs, piglets, and calves, and that continued high-quality feed is necessary for high egg production and milk yield when the animals reach adulthood. In crop plants such as grains, adequate soil moisture and nutrients are necessary for sustained high yields.

Environmental factors not only affect the average phenotype for complex traits, but they also affect the variation in phenotype from one individual to the next. For example, most fields of corn you see planted along the roadside come from seeds that are genetically identical to one another, yet there is phenotypic variation in complex traits like plant height (**Fig. 17.3**). Because the plants are genetically identical, the differences in phenotype result from differences in the environment. Some parts of the field may receive more sunlight than others, and some parts may have better water drainage. No matter how uniform an environment may seem, there are always minor differences from one area to the next, and these differences can result in variation in complex traits. In the example in **Fig. 17.3**, the plants in the foreground are shorter than the others because that corner of the field has poorer

drainage, and the plants growing there have to compete for nutrients with the grass growing nearby.

Source: Bruce Leighty/Getty Images.

FIG. 17.3 Phenotypic variation due to variation in the environment. Genetically identical corn plants vary in height because of variation in exposure to sun and in soil composition at different locations in the same field.

Environmental effects on complex traits in animals can be observed in true-breeding, homozygous strains such as those used by Mendel in his experiments with pea plants. Such true-breeding strains are called **inbred lines**, and they are often used for research. Even though all animals in any inbred line are genetically identical and are caged in the

same facility and fed the same food, there is variation from one animal to the next. In one study of cholesterol levels in an inbred line of mice, for example, average serum cholesterol was 120 mg/dl (milligrams per deciliter), but the range was 60–180 mg/dl. Because the mice are genetically identical, the variation in serum cholesterol resulted entirely from variation in the environment.

## Complex traits are affected by multiple genes.

Most complex traits are affected by many genes, in contrast to Mendel's traits, which are primarily affected by only one. Therefore, in complex traits the familiar phenotypic ratios such as 3 : 1 that Mendel saw when he crossed two true-breeding strains with contrasting characters are not observed. For complex traits, the effects of individual genes are obscured by variation in phenotype that is due to multiple genes affecting the trait and also due to the environment. The number of genes affecting complex traits is usually so large that different genotypes can have very similar phenotypes, which also makes it difficult to see the effects of individual genes on a trait.

In a few traits, however, the effects of the environment are minor and the number of genes is small, and in these cases, the genetic basis of the trait can be analyzed. A classic example, studied by Herman Nilsson-Ehle about a century ago, concerns the color of seed casing in wheat (which give the seeds their color), which ranges from nearly white to dark red ([Fig. 17.4](#)). His experiment demonstrated that complex traits are subject to the same laws that Mendel worked out for single-gene traits, but that the inheritance patterns are more difficult to

see because of the number of genes involved.

Two plants heterozygous for each of three unlinked genes affecting the color of seed casing are crossed.

$Aa Bb Cc \times Aa Bb Cc$

The genes act cumulatively to determine the intensity of red coloration; in this example, each upper-case allele in the genotype adds more red to the phenotype.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 17.4 Multiple genes contributing to a complex trait. Three unlinked genes, each with two alleles, influence the intensity of red coloration of the seed casing in wheat.

In studying seed color in true-breeding varieties and their first-generation and second-generation hybrids, Nilsson-Ehle realized that the relative frequencies of different shades of red color could be explained by the effects of three genes that undergo independent assortment, as illustrated by the Punnett square shown in [Fig. 17.4](#). Each of the genes has two alleles, designated by combinations of upper-case and lower-case letters. In the development of seed color, each upper-case allele in a genotype intensifies the red coloration in an additive fashion. Altogether there are seven possible phenotypes, ranging from a phenotype of 0 (nearly colorless, genotype *aa bb cc*) to 6 (dark red, genotype *AA BB CC*).

Nilsson-Ehle first crossed true-breeding dark red plants (*AA BB CC*) with true-breeding colorless plants (*aa bb cc*) to obtain the hybrids with genotype *Aa Bb Cc*. He then crossed the hybrids together, which is the cross shown at the top of [Fig. 17.4](#). Because the three genes show independent assortment ([Chapter 15](#)), the distribution of phenotypes expected in progeny from the cross *Aa Bb Cc* × *Aa Bb Cc* is as shown in the Punnett square. The bar graph below the Punnett square shows the seed-color phenotypes and their relative proportions, from which Nilsson-Ehle inferred three genes with independent assortment. The distribution of seed-color phenotypes is approximated by a bell-shaped curve known as a [normal distribution](#). The phenotypes of many complex traits, including human height, conform to the normal

distribution. Nilsson-Ehle's seed-color case is exceptional in that virtually all complex traits are affected by many more genes than three (in the case of human height, hundreds, as discussed below).

When differences in phenotype due to the environment can be ignored, the genetic variation affecting complex traits can be detected more easily. And when studying inbred lines, differences in phenotype due to genotype can be ignored because all individuals have the same genotype, and the effects of environment can be observed. In most cases, however, both genetic variation and environmental variation among individuals are present, and it is difficult to quantify how much variation in phenotype is due to genes and how much is due to environment.

Keep in mind that complex traits are not really more “complex” than any other biological trait. The term is used merely to imply that both genetic factors and environmental factors contribute to variation in phenotype among individuals. Just as there are environmental factors that affect complex traits such as height, so there are genetic factors that affect height. Similarly, just as an environmental risk factor increases the likelihood of a common disease, so does a genetic risk factor predispose an individual to the condition. For example, the human gene *ApoE* encodes a protein that helps transport fat and cholesterol. Certain alleles of *ApoE* are associated with high levels of cholesterol, and one particular allele is a genetic risk factor for Alzheimer's disease, the most common serious form of age-related loss of cognitive ability. Lifestyle environmental factors such as diet, physical exercise, and mental stimulation are also thought to play a role

in the risk of Alzheimer's disease.

## The relative importance of genes and environment can be determined by differences among individuals.

For any one individual, it is impossible to specify the relative roles of genes and environment in the expression of a complex trait. For example, in an individual 66 inches tall, it would be meaningless to attribute 33 inches of height to parentage (genes) and 33 inches of height to nutrition (environment). This kind of partitioning makes no sense because genes and environment act together so intimately in each individual that their effects are inseparable. To attempt to separate them for any individual would be like asking to what extent it is breathing or oxygen that keeps us alive. Both are important, and both must take place together if we are to live.

It is nevertheless possible to separate genes and environment in regard to their effects on the *differences*, or variation, among individuals within a particular population. For some traits, the variation seen among individuals is due largely, if not exclusively, to differences in the environment. For other traits, the variation is due mainly to genetic differences. In the case of human height, roughly 60% of the variation among individuals of the same sex is due to genetic differences, and the remaining 40% to differences in their environment, primarily differences in nutrition during their years of growth.

## Genetic and environmental effects can

## interact in unpredictable ways.

One of the features of complex traits is that genetic and environmental effects may interact, often in unpredictable ways. Consider the example shown in [Fig. 17.5](#). In this experiment, two genetically different strains of corn were each grown in a series of soils in which the amount of nitrogen had been enriched by the growth of legumes. The yield of strain 1 varies little across these different environments. The yield of strain 2, however, increases dramatically with soil nitrogen. Each of the lines is known as a [norm of reaction](#), which for any genotype graphically depicts how the environment (shown on the x-axis) affects phenotype (shown on the y-axis) across a range of environments. Note that in one case in [Fig. 17.5](#), the environment has little to no effect on the phenotype (the norm of reaction is nearly flat), but in the other it has a very noticeable effect. In cases such as strain 2, it is impossible to predict the phenotype of a given genotype without knowing what the environmental conditions are and how the phenotype changes in response to variation in the environment.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 17.5 Genotype-by-environment interaction for grain yield in corn. The effect of soil nitrogen on grain yield is minimal in strain 1, but dramatic in strain 2. *Data courtesy of J. W. Dudley.*

Such variation in the effects of the environment on different genotypes is known as **genotype-by-environment interaction**. This type of interaction is important because it implies that the effect of a genotype cannot be specified without knowing the environment, and the other way around. A further implication is that there may be no genotype that is the “best” across a broad range of environments, and likewise no environment that is “best” for all genotypes. For complex traits, phenotype depends on both genotype *and* environment. For the strains of corn in [Fig. 17.5](#), for example, which strain is “better” depends on the soil nitrogen. With little nitrogen enrichment, strain 1 is better; at intermediate values, both strains yield about the same; and with high nitrogen enrichment, strain 2 is better. In this case, knowing the norms of reaction and recognizing the magnitude and direction of genotype-by-environment interaction, allows each farmer to use the strains likely to perform best under the available conditions of cultivation.

Genotype-by-environment interaction makes the interplay between genes and the environment difficult to predict. An example of genotype-by-environment interaction affecting obesity is shown in [Fig. 17.6](#). The animals shown are adults of two inbred lines of mice. When fed a normal diet, both inbred lines grow to about the same size. When fed a high-fat diet, however, the inbred line A becomes obese, but inbred line B does not. Hence, it is not genotype alone that causes

obesity in line A because with a normal diet, line A does not become obese. Nor is it a high-fat diet alone that causes obesity, because the high-fat diet does not cause obesity in line B. Rather, the obesity in line A results from a genotype-by-environment interaction (which in this case is a genotype-by-diet interaction).

*Source: Phil Jones/Georgia Regents University.*

FIG. 17.6 Genotype-by-environment interaction for obesity in mice. When fed a normal diet, both inbred lines grow to about the same size. When fed a high-fat diet, mouse A becomes obese but mouse B does not.

#### Self-Assessment Questions

1. Why are some complex traits also called quantitative traits?
2. What is an example of a complex trait?
3. What are some factors that influence variation in complex traits?

4. Why does it not make sense to try to separate the effects of genes (“nature”) and the environment (“nurture”) in a single individual, whereas it does make sense to separate genetic and environmental effects on differences among individuals?
5. Why can the effect of a genotype on a phenotype not always be determined without knowing what the environment is? Why can the effect of a particular environment on a phenotype not always be determined without knowing what the genotype is?

## 17.2 RESEMBLANCE AMONG RELATIVES

Mendel had many advantages over Galton in his studies of inheritance. Mendel's peas were true breeding, produced a new generation each year, and yielded large numbers of progeny. The environment had a negligible effect on the traits, and alleles of a single gene were responsible for variation of each trait. Mendel's crosses yielded simple ratios such as 3 : 1 or 1 : 1, which could be interpreted in terms of segregation of dominant and recessive alleles.

By contrast, Galton studied variation in such traits as height in humans. Humans are obviously not true breeding, have a long generation time, and produce few offspring. Most importantly, for complex traits such as height, both genetics and environment affect the phenotype. Two individuals with the same genotype may have a different phenotype because of differences in the environment, and two individuals in exactly the same environment may differ in phenotype because of differences in genotype. In one respect Galton had an advantage, though: whereas most simple Mendelian traits are relatively uncommon, Galton's traits are readily observed in everyday life. What did Galton discover?

**For complex traits, offspring resemble parents but show regression toward the mean.**

Galton's observations are as important in understanding complex traits

as Mendel's are in understanding single-gene traits. He studied many complex traits, including human height, strength, and various other physical characteristics, such as the number of fingerprint ridges. The discovery he regarded as fundamental resulted from his data on adult height of parents and their progeny ([Fig. 17.7](#)). Galton noted that each category of parent (tall or short) produced a range of progeny forming a distribution with its own [mean](#) (the average value).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 17.7 Galton's data showing distribution of height of offspring of (a) the tallest parents and (b) the shortest parents. *Data from F. Galton, 1888, "Correlations and Their Measurement, Chiefly from Anthropometric Data," Proceedings of the Royal Society, London 45:135–145, reprinted in K. Pearson, 1920, "Notes on the History of Correlation," Biometrika 13:25–45.*

The bar graph in [Fig. 17.7a](#) shows the distribution of height among the progeny of the tallest parents in the population Galton studied, whose mean height is 72 inches. The mean height of the offspring is 71 inches, which is greater than the mean height of the whole population of the study (68.25 inches) but less than that of the parents. The bar graph in [Fig. 17.7b](#) is the distribution of height of progeny of the shortest parents, whose mean equals 66 inches. In this case, the mean height of the progeny is 67 inches, which is less than the mean height of the population but greater than that of the parents. Note, however, that *some* of the offspring of tall parents are taller than their parents, and likewise *some* of the offspring of short parents are shorter than their parents. It is only *on average* that the height of the offspring is less extreme than that of the parents.

Galton regarded this observation as his most important discovery and reported it in 1886. Today, we call it [regression toward the mean](#). The offspring exhibit a mean phenotype that is closer to the population mean than the phenotype of the parents. In other words, when the mean height of the parents is *smaller* than the population mean, then the mean height of the offspring is *greater* than that of the parents (but smaller than the population mean). Likewise, when the mean height of the parents is *greater* than the population mean, then the mean height of the offspring is *smaller* than that of the parents (but greater than the population mean).

Regression toward the mean is observed for two reasons. The first is that during meiotic cell division ([Chapter 11](#)), segregation and recombination break up combinations of genes that result in extreme

phenotypes, such as very tall or very short, that are present in the parents. The second reason is that the phenotype of the parents results not only from genes but also from the environment. Environmental effects are not inherited, so any effect of the environment on the parents' phenotypes is not transmitted to the offspring. For example, if the parents are tall or short purely because of an environmental effect such as better or worse nutrition, then the mean height of the offspring will be equal to the population mean.

## Heritability is the proportion of the total variation due to genetic differences among individuals.

The data points in red in [Fig. 17.8](#) show that regression toward the mean occurs across the full range of heights and not only at the extremes as in [Fig. 17.7](#). For convenience in visualization, parents with similar heights have been grouped and averaged (x-axis), and for each group of parents the heights of their offspring have also been averaged (y-axis). The line in red is the *regression line* that best fits the data.

FIG. 17.8 Regression toward the mean. Galton's data on the average adult height of parents and that of their offspring show that offspring mean height (red line) falls between the parental mean (blue line) and the population mean (black line).

Let's contrast the regression line in [Fig. 17.8](#) with two hypothetical extremes. One extreme is shown by the blue line with a slope of 1.0. This is the regression line expected when all the variation in height results from genetic differences among individuals and when height is determined by a large number of genes, each with small effect and with no dominance or gene interaction. (The genetic model is exactly like that shown in [Fig. 17.4](#) but with many more genes.) Under these assumptions, the mean height of the offspring will equal the mean height of the parents, and any deviations from the blue line will be due entirely to chance.

The black line in [Fig. 17.8](#) with a slope of 0.0 represents the opposite extreme when all variation in height results from

environmental differences among individuals. As long as environmental effects are not transmitted from one generation to the next, the mean phenotype of the offspring will be equal to the mean of the population as a whole, irrespective of the phenotypes of the parents. Although environmental effects are usually not transmitted in plant and animal populations, human populations are exceptional in showing **cultural transmission** of some environmental effects. For example, the average wealth of the offspring of rich parents is greater than that of the offspring of poor parents, and this difference is obviously due to transmission of the parents' money, not their genes.

How much of the variation in height among individuals is due to genetic differences, and how much is due to environmental differences? The answer to this question is found in the slope of the regression line, which in Galton's data equals 0.60. Because a slope of 0.0 implies variation due only to the environment and a slope of 1.0 implies variation due only to genetics, a slope of 0.6 implies that 60 percent of the variation in height is due to genetic differences among individuals and 40 percent due to environmental differences among individuals.

The proportion of the total variation in the trait that is due to genetic differences among individuals is called the **heritability** of the trait. Thus, the slope of the regression line of progeny mean against parental mean is an estimate of the heritability of adult height (0.6 in Galton's data). For a complex trait, the heritability determines how closely the mean of the progeny resembles that of the parents. The similarity between first cousins and other types of relatives also depends on the

heritability.

The term “heritability” is often misinterpreted. The problem is that, in nonscientific contexts, the word means “the capability of being inherited or being passed by inheritance.” This definition suggests that heritability has something to do with the inheritance of a trait. But “heritability” as used for complex traits means no such thing. It refers only to the *variation* in a trait among individuals, and specifically to the proportion of the variation among individuals in a population due to differences in genotype.

Hence, a heritability of 100% does not imply that the environment has no effect on the trait. As emphasized earlier, the environment is always important—without oxygen, you wouldn’t be reading this. What a heritability of 100% means is that *variation* in the environment does not contribute to differences among individuals in a specific population. For example, if genetically different strains of chrysanthemums are grown in a greenhouse and subject to identical environmental conditions, then differences in flowering time have to be due to genetic differences, and the heritability of the trait would be 100%. Similarly, a heritability of 0% does not imply that genotype has no effect on the trait. A heritability of 0% merely means that differences in genotype do not contribute to the *variation* in the trait among individuals in a specific population. If genetically identical strains of chrysanthemums are grown in different environments, then differences in flowering time must be due to the environment, and heritability would be 0%.

Heritability is not an intrinsic property of a trait. For chrysanthemum flowering time, the heritability in one case was 100% and in the second 0%. Heritability applies only to the trait in a particular population across the range of environments that exist at a specific time. Similarly, the heritability depicted by the slope of the red line in [Fig. 17.8](#) applies only to the population studied (205 pairs of British parents and their 930 adult offspring, in the late nineteenth century) and may be larger or smaller in different populations at different times. In particular, the magnitude of the heritability cannot specify how much of the difference in average phenotype *between* two populations is due to genotype and how much due to environment.

If the heritability of a trait can change depending on the population and the conditions being studied, why is it useful? Heritability is important in evolution, particularly in studies of artificial selection, a type of selective breeding in which only certain chosen individuals are allowed to reproduce ([Chapter 20](#)). Practiced over many generations, artificial selection can result in considerable changes in morphology or behavior or almost any trait that is selected. The large differences among breeds of pigeons and other domesticated animals prompted Charles Darwin to point to artificial selection as an example of what natural selection could achieve. Heritability is important because this quantity determines how rapidly a population can be changed by artificial selection. A trait with a high heritability responds rapidly to selection, whereas a trait with a low heritability responds slowly or not at all.

6. Graph a trait, such as human height, with height on the x-axis and number of individuals on the y-axis, and describe the shape of the resulting graph.
7. How might you go about determining the relative importance of genes and the environment for variation in risk for a complex trait such as type 2 diabetes?
8. What is “regression toward the mean” and why does it occur for complex traits?
9. Does regression toward the mean imply that the human population is getting shorter over time?
10. What is the heritability of a trait and why does the heritability of a given trait depend on the population being studied?

## 17.3 TWIN STUDIES

Studies of twins are one way to separate the effects of genotype and environment on phenotypic differences among individuals. Depending on whether they arise from one or from two egg cells, twins can be **monozygotic (MZ)** twins or **dizygotic (DZ)** twins. MZ twins arise from a single fertilized egg (the zygote), which, after several rounds of cell division, separates into two distinct but genetically identical embryos. Often strikingly similar in overall appearance (**Fig. 17.9a**), MZ twins are commonly known as identical twins. However, this is a misnomer. MZ twins differ from one another in many ways because of environmental effects. Nevertheless, MZ twins have stimulated the imagination since antiquity, inspiring stories by the Roman playwright Plautus, William Shakespeare (himself the father of twins), Alexander Dumas, Mark Twain, and many others.

Sources: a. Craig Gaffield/AP Images; b. Wendy Connett/Getty Images.

**FIG. 17.9** Twins. (a) Monozygotic twins arise from a single fertilized egg and are genetically identical. (b) Dizygotic twins arise from two different fertilized eggs and are no more closely related than other pairs of siblings.

In contrast, DZ twins (also called fraternal twins) result when two

separate eggs, produced by a double ovulation, are fertilized by two different sperm. Whereas MZ twins are genetically identical, DZ twins are only as closely related as any other pair of siblings ([Fig. 17.9b](#)).

## Twin studies help separate the effects of genes and environment in differences among individuals.

The utility of twins in the study of complex traits derives from the genetic identity of MZ twins. Whereas differences between DZ twins with regard to any trait may arise because of genetic or environmental factors (or genotype-by-environment interactions), differences between MZ twins must arise only from environmental factors because the twins are genetically identical. Consequently, if variation in a trait has an important genetic component, then MZ twins will be more similar to each other than DZ twins are similar to each other. But if the genetic contribution to variation is negligible, then MZ twins will not be more similar to each other than DZ twins are to each other. One complication of twin studies is that half of all DZ twins are of the opposite sex whereas MZ twins are always of the same sex. This issue is easily resolved by studying only same-sex DZ twins. Another caveat of twin studies is that the environment of MZ twins may be more similar than that of DZ twins; this can be remedied in some cases by studying MZ twins separated from each other shortly after birth and raised in different environments.

For complex traits, such as depression or diabetes, the extent to which twins are alike is measured according to the [concordance](#) of the

trait, which is defined as the percentage of cases in which both members of a pair of twins show the trait when it is known that at least one member shows it. The relative importance of genetic and environmental factors in causing differences in phenotype can be estimated by comparing the concordances of MZ and DZ twins. A significantly higher concordance rate for a given trait for MZ twins compared with that for same-sex DZ twins suggests that the trait has a strong genetic component. Similar concordance rates for MZ and same-sex DZ twins suggest that the genetic component is less important.

In the study of concordance, twin pairs in which neither member is affected contribute no information, and these twin pairs must be removed from the analysis. The concordance is based solely on twin pairs in which one or both members express the trait. To take a concrete example, let us symbolize each member of a MZ twin pair as a closed square (■) if the member shows the trait and as an open square (□) if the member does not show the trait. Then, in any sample of MZ twins, there are three possibilities, illustrated with data for type 2 diabetes:

- ■ 20 MZ twin pairs, both members showing type 2 diabetes
- □ 30 MZ twin pairs, only one member showing type 2 diabetes
- □ 500 MZ twin pairs, neither member showing type 2 diabetes

In this example, the 500 twin pairs who do not show the trait provide no information. The concordance is based only on the first two types of twin pairs, among which in 20 pairs both members show the

trait and in 30 pairs only one shows the trait. In this case the concordance among MZ twins is  $20/(20 + 30) = 40\%$ . Among same-sex DZ twins, by contrast, the observed concordance for type 2 diabetes is only 10%. The difference in concordance between MZ and DZ twins (40% for MZ versus 10% for DZ) implies that differences in the risk of type 2 diabetes have an important genetic component. Furthermore, the observation that the concordance for MZ twins is much less than 100% implies that environmental factors unique to each twin in a pair (factors that we now know to include diet and exercise) are also important in the risk of type 2 diabetes. That the MZ concordance is not 100% implies that both genes and environment —“nature” *and* “nurture”—play important roles in the differences in risk.

**Figure 17.10** uses the complex trait schizophrenia as an example to illustrate how the MZ and DZ concordance rates are affected by genetic factors, environmental factors common to members of each twin pair, and environmental factors that are unique to each twin in a pair.

#### HOW DO WE KNOW?

### FIG. 17.10

What is the relative importance of genes and of the environment for complex traits?

#### BACKGROUND

Twin studies remain important for assessing the relative importance of “nature” (genotype) and “nurture” (environment) in determining variation among individuals for complex traits. The idea of using twins to

distinguish nature from nurture is usually attributed to English biologist Francis Galton because of an article he wrote about twins in 1875. In fact, the modern twin study does not trace to Galton but to Curtis Merriman in the United States and Hermann Siemens in Germany, who independently hit upon the idea in 1924. In Galton's time, it was not known that there are genetically two different kinds of twins.

#### EXPERIMENT

The rationale of a twin study is to compare MZ twins with same-sex DZ twins. In principle, MZ twins differ only because of environment, whereas DZ twins differ because of genotype as well as environment. The extent to which DZ twins differ more from each other than MZ twins differ from each other measures the effect of fewer shared genes in the DZ twins. Some twin studies focus on twins reared apart in order to compensate for shared environmental influences that may be stronger for MZ twins than for DZ twins.

#### RESULTS

Part (a) in the illustration presents MZ and DZ data for schizophrenia. For simplicity, we have imagined a sample of 1000 MZ twins and 1000 DZ twins who show the same concordance rates as actual studies of tens of thousands of twin pairs. The concordance between twins is the fraction of twin pairs in which both twins show the trait among all those pairs in which at least one twin shows the trait. Part (b) shows the data as a bar graph. Roughly speaking, the difference in the concordance between MZ and DZ twins is a measure of the relative importance of genotype. The concordance for MZ twins is less than 1.0 because environmental factors unique to each twin in an MZ pair affect concordance.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## CONCLUSION

The example of schizophrenia shown here indicates large differences in the importance of genotype versus environment for this complex trait. This result is typical of the most common human diseases, all of which are complex traits.

## FOLLOW-UP WORK

Because of complications due to cultural inheritance, twin studies must always be interpreted in light of other studies comparing complex traits among individuals with various degrees of genetic relatedness. On the whole, twin studies of complex traits have yielded results that are consistent with other available evidence.

SOURCES Polderman, T. J. C. *et al.* 2015. "Meta-analysis of the Heritability of Human Traits Based on Fifty Years of Twin Studies." *Nature Genetics* 47:702–709; McGue, M., and T. J. Bouchard, Jr. 1998. "Genetic and Environmental Influences on Human Behavioral Differences." *Annual Review of Neuroscience* 21:1–24.

[Table 17.1](#) shows concordance rates for other complex traits. Note that for handedness, measles, or death from acute infection the concordance rates for MZ twins are very similar to those for same-sex DZ twins. Equality of the MZ and DZ concordance implies that there is no significant genetic component to variation in the trait, at least insofar as can be determined from twin studies. (Many students are surprised to learn that handedness does not have a detectable genetic component.) For infectious diseases, exposure to the disease agents in the environment is the determinant. With measles, for example, the data imply that when one twin catches measles, the other will very likely catch it, too, and it does not matter whether the twins are MZ or DZ.

**TABLE 17.1 Twin Concordance Rates for Several Traits**

| DISORDER                         | CONCORDANCE IN<br>MONOZYGOTIC TWINS (%) | CONCORDANCE IN<br>DIZYGOTIC TWINS (%) |
|----------------------------------|-----------------------------------------|---------------------------------------|
| High blood pressure              | 25                                      | 7                                     |
| Asthma                           | 47                                      | 24                                    |
| Rheumatoid arthritis             | 34                                      | 7                                     |

### Self-Assessment Questions

11. What is twin concordance?
12. How can twin studies be used to investigate the importance of genetic and environmental factors in the expression of a trait?

## 17.4 COMPLEX TRAITS IN HEALTH AND DISEASE

Much evidence beyond twin studies implies an important role for particular alleles as risk factors for diabetes, high blood pressure, asthma, rheumatoid arthritis, epilepsy, schizophrenia, clinical depression, autism, and many other conditions. These are all complex traits, affected by genotype, environment, and genotype-by-environment interactions.

Even the most common birth defects are affected by multiple genetic risk factors. The most common birth anomalies and the numbers of affected babies born in the United States each year—collectively more than 35,000—are indicated in [Fig. 17.11](#). About 20% of these anomalies are due to an extra chromosome. Trisomy 21 (Down syndrome) is by far the most common of these chromosome-number abnormalities ([Chapter 11](#)). Another roughly 10% are due to defects in metabolism, many of which—among them cystic fibrosis, sickle-cell anemia, and phenylketonuria (the inability to break down the amino acid phenylalanine)—are rare simple Mendelian disorders. Birth anomalies due to extra or missing chromosomes and those due to single-gene Mendelian inheritance are not considered complex traits in terms of their inheritance. Together these account for about 30% of the of birth anomalies in [Fig. 17.11](#). Most (70%) birth anomalies in [Fig. 17.11](#) are inherited as complex traits that are affected by both genetic and environmental risk factors.

## Most common diseases and birth defects are affected by many genes, each with a relatively small effect.

Because the most common birth anomalies as well as childhood and adult disorders are complex traits, biologists are keenly interested in identifying the genes that contribute to differences in risk, understanding what these genes do, and translating this knowledge into prevention or treatment. They have therefore begun to apply modern molecular methods—genome sequencing ([Chapter 13](#)), genome

annotation ([Chapter 13](#)), and genotyping ([Chapter 14](#))—to identifying genes affecting complex traits.

The identification of genes affecting complex traits is not only a major goal of much current research in human genetics, but also in the genetics of domesticated animals and plants. Gene identification is also important in model organisms used in research, especially the laboratory mouse. Much is already known about these model organisms and they are easily manipulated, making it possible to discover the molecular mechanisms by which genes affecting complex traits exert their effects.

The study of complex traits has reached a stage at which patterns are beginning to emerge. Many of these patterns can be seen in the chromosome map in [Fig. 17.12](#), which shows the location of genes in the human genome that affect cholesterol levels. The first observation is that many genes contribute to amounts of different types of cholesterol in humans—specifically, more than 50 genes contribute to the level of HDL (high-density lipoproteins, or “good cholesterol”), LDL (low-density lipoproteins, or “bad cholesterol”), and triglycerides. A second observation is that many of these genes affect two or even all three of the types of molecule. (A single gene that has multiple effects is said to show [pleiotropy](#).) Third, many of the genes occur in clusters, being physically close together in the same chromosome. Clustering of genes shows that many genes arose through the process of duplication of a single gene followed by divergence over time, generating a family of genes near one another with related functions ([Chapter 14](#)).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 17.12 Genes affecting the level of serum cholesterol in the human genome. Data from X. Wang and B. Paigen, 2005, "Genetics of Variation in HDL Cholesterol in Humans and Mice," *Circulation Research* 96:27–42.

Two other patterns are not visible in [Fig. 17.12](#). One is that many of the genes show epistasis. Epistasis occurs when multiple genes act in the same pathway to affect a trait ([Chapter 15](#)). Finally, the functions of many of the genes that contribute to a complex trait are often not known. Some of the genes in [Fig. 17.12](#) affect serum cholesterol through known metabolic pathways, but many others work through unknown pathways. Many of the human genes shown have counterparts in the mouse genome that have similar effects on serum cholesterol, so these genes are open to direct experimental investigation.

A principle that is not evident in [Fig. 17.12](#) is that the effects of each of the genes on cholesterol levels are very unequal. Some have relatively large effects, whereas others have small ones. The distribution of the magnitude of gene effects for complex traits resembles that shown in [Fig. 17.13](#). The axes are labeled only in relative terms, because the actual numbers and effect sizes differ from one trait to the next. However, the main point is that for most genes that contribute to a complex trait, the magnitude of their individual effects is typically quite small. The magnitude of the effects of individual genes also often differs between the sexes, which helps explain why complex traits so often differ in prevalence or severity between males and females.

## Human height is affected by hundreds of genes.

For most complex traits, the genes that have been identified to date account for only a relatively small fraction of the total variation in the trait. One extreme example is adult height. An enormous amount of data is available for height, not because height has been studied extensively for its own sake, but because in studies of common diseases the height of each individual is recorded, and hence data on height are available without additional effort or expense.

In one analysis, results from 79 separate studies were combined. These studies included more than 250,000 individuals of European ancestry who were genotyped for common nucleotide variants (SNPs) at about 3 million nucleotide sites. The analysis identified 697 genes affecting height. Some of these genes are known to affect skeletal

development, growth hormones, or other growth factors, but most have no obvious connection to the biology of growth. Some of the genes had previously been identified by studies of rare mutations that have pronounced effects on skeletal growth, either in human families or in laboratory mice. An unexpected finding was that a few genes affecting height are known to be associated with bone mineral density, obesity, and rheumatoid arthritis. These and many other of the genes identified might affect height indirectly.

The 697 genes for height identified among the 250,000 individuals account for about 60% of the genetic variation in height, a number that suggests that many more genes with still smaller effect also contribute to variation in height. And this analysis does not address at all the effects of the environment on human height, nor genotype-by-environment interactions, which likely play an important role as well. Complex traits therefore require sophisticated studies to tease apart all the genetic and environmental factors that play a role.

### CASE 3 YOUR PERSONAL GENOME: YOU, FROM A TO

T

## Can personalized medicine lead to effective treatments of common diseases?

The multiple genetic and environmental factors affecting complex traits imply that different people can have the same disease for

different reasons. For instance, one person might develop breast cancer because of a mutation in the *BRCA1* or *BRCA2* genes, whereas another might develop breast cancer because of other genetic risk factors or even environmental ones. Similarly, one person might develop emphysema because of a mutation in the gene that encodes the enzyme alpha-1 antitrypsin ( $\alpha$ 1AT) ([Chapter 14](#)), and another might have emphysema as a result of cigarette smoking. Other examples where the same disease can be the result of different underlying genetic or environmental factors include elevated cholesterol levels, high blood pressure, and depression. Because the underlying genetic basis for the same disease may be different in different patients, some patients respond well to certain drugs and others do not.

The traditional strategy for treating diseases is to use the same medicine for the same disease. However, because we now know that the same disease may have different causes, another possibility has emerged: identifying each patient's genotype for each of the relevant genes and then matching the treatment to the genetic risk factors in each patient. The approach that matches the treatment to the patient, not the disease, is known as [personalized medicine](#) or [precision medicine](#). (Prescription eyeglasses are a 400-year-old type of personalized medicine.)

Personalized medicine not only aims to identify ahead of time medicine that will work effectively, but also to avoid medicines that may lead to harmful side effects, even death. Advertisements and enclosures with prescription drugs enumerate long lists of side effects that you may get if you take a particular medicine. At present, it is

difficult to know in advance who will get one or more of these side effects and who won't—that is, the side effects of taking medicine are themselves complex traits and the result of many underlying genetic and environmental factors. If we could identify ahead of time those patients who will respond negatively to a particular medicine and those who won't, we could minimize potentially harmful effects of medicines on certain individuals.

Someday, it may be possible to determine each patient's genome sequence quickly, reliably, and cheaply. At present, personalized medicine is restricted to studies of a few key genes known to have important effects on treatment outcomes. In the treatment of asthma, for example, some of the differences in response to albuterol inhalation have been traced to genetic variation in the gene *ADRB2*, encoding the  $\beta$ -(beta)-2-adrenergic receptor. Similarly, certain drugs used in the treatment of Alzheimer's disease are less effective in women with a particular apolipoprotein E (*APOE*) genotype than in other classes of patients. Also, more than half of the cases of muscle weakness occurring as an adverse effect of drug treatment used to control high cholesterol can be traced to genetic variation in the gene *SLCO1B1*, which encodes a liver transport protein. Certain variants of this protein have decreased ability to transport the drug, so higher concentrations remain in the blood and there is a risk of muscle weakness.

Other factors in addition to genes are involved in these disorders, but genes play an important role. Knowledge of a patient's genotype can help guide treatment. These are only a few of many examples, but they demonstrate the substantial potential benefits of personalized

medicine.

#### Self-Assessment Questions

13. When genes for complex traits have effects that are distributed as shown in [Fig. 17.13](#), which are easier to identify: those that are numerous with small effects, or those that are few with large effects?
14. What is personalized medicine and how does it relate to complex traits such as human diseases?

## CORE CONCEPTS SUMMARY

**17.1 HEREDITY AND ENVIRONMENT:** Complex traits are those influenced both by the action of many genes and by environmental factors.

Complex traits that are measured on a continuous scale, such as human height, are called quantitative traits. [page 363](#)

It is usually difficult to assess the relative roles of genes and the environment (“nature” versus “nurture”) in the production of a given trait in an individual, but it is reasonable to consider the relative roles of genetic and environmental variation in accounting for differences among individuals for a given trait. [page 365](#)

The relative roles of genes and environment in causing differences in phenotype among individuals differ among traits. For some traits (such as height), genetic differences are the more important source of variation, whereas for others (such as cancer), environmental differences can be the more important. [page 365](#)

Genetic and environmental factors can interact in unpredictable ways, resulting in genotype-by-environment interactions. [page 365](#)

**17.2 RESEMBLANCE AMONG RELATIVES:** Genetic effects on complex traits are reflected in resemblance between relatives.

In an analysis of heights of parents and offspring, Galton observed regression toward the mean, in which the offspring exhibit an average phenotype that is less different from the population mean than that of the parents. [page 366](#)

“Heritability” refers to the proportion of the total variation in a trait that can be attributed to genetic differences among individuals.

[page 368](#)

The heritability of a given trait can differ among populations because of differences in genotype or environment. [page 368](#)

**17.3 TWIN STUDIES:** Twin studies help separate the effects of genotype and environment on variation in a trait.

Monozygotic (MZ), or identical, twins result from the fertilization of a single egg and are genetically identical. [page 369](#)

Dizygotic (DZ), or fraternal, twins result from the fertilization of two eggs and are genetically related to each other in the same way that other siblings are related to each other. [page 369](#)

“Concordance” refers to the percentage of cases in which both members of a pair of twins show the trait when it is known that at least one member shows it. [page 369](#)

Comparisons of concordance rates of MZ twins and concordance rates of DZ twins can help to determine to what extent variation in a particular trait has a genetic component. [page 369](#)

**17.4 COMPLEX TRAITS IN HEALTH AND DISEASE:** Many common diseases and birth defects are affected by multiple genetic and environmental risk factors.

Complex traits are often influenced by many genes with multiple, interacting, and unequal, effects. [page 372](#)

Hundreds of genes affect human height. [page 373](#)

Personalized medicine tailors treatment to an individual's genetic makeup. [page 373](#)

## CHAPTER 18 Genetic and Epigenetic Regulation

Lawrence Berkeley National Laboratory/Science Source

---

## CORE CONCEPTS

### **18.1 CHROMATIN TO MESSENGER RNA IN EUKARYOTES:**

Gene expression in eukaryotes can be regulated at the level of DNA packaging in chromosomes, transcription, and RNA processing.

### **18.2 MESSENGER RNA TO PHENOTYPE IN EUKARYOTES:**

After an mRNA is exported to the cytoplasm, gene expression in eukaryotes can be regulated at the level of mRNA stability, translation, and posttranslational modification of proteins.

### **18.3 TRANSCRIPTIONAL REGULATION IN PROKARYOTES:**

Gene expression in prokaryotes can be regulated at the level of transcription in response to environmental conditions.

---

In [Chapter 17](#), we learned that complex traits are not determined by single genes with simple Mendelian inheritance. The traits we usually encounter in ourselves or in others, such as height, weight, diabetes, and high blood pressure, are influenced by multiple genes that interact with one another and with environmental factors, such as diet and exercise. The number of genes influencing complex traits can be large. For example, hundreds of genes contribute to adult height. The activities of these genes must be coordinated in time (at a particular point in development) and place (in a particular type of tissue). For example, growth to normal adult height requires that the production of growth hormone be coordinated in time and place with the production of growth-hormone receptor.

In [Chapters 3](#) and [4](#), we outlined the basic steps of information flow

in a cell, focusing on transcription and translation. In these processes, DNA is a template for the production of messenger RNA (mRNA), which itself is the template for the synthesis of a protein. For these processes to work in a living organism to produce the traits that we see, they must be coordinated so that genes are only **expressed**, or turned on, in the right place and time, and in the right amount. In a multicellular organism, for example, certain genes are expressed in some cells but not in others. Genes encoding muscle actin and myosin are turned on in muscle cells but not in liver or kidney cells. Even for single-celled organisms like bacteria, certain genes are expressed only in response to environmental signals, such as the availability of nutrients, as we discuss in [section 18.3](#).

**Gene regulation** encompasses the ways in which cells control gene expression. It can be thought of as the *where?* *when?* and *how much?* of gene expression. Where (in which cells) are genes turned on? When (during development or in response to changes in the environment) are they turned on? How much gene product is made? This chapter provides an overview of the most common ways in which gene expression is regulated.

One of the important principles we discuss is that gene regulation can occur at almost any step in the path from DNA to mRNA to protein—at the level of the chromosome itself, by controlling transcription or translation, and, perhaps surprisingly, even after the protein is made. Each of these steps or levels of gene expression may be subject to regulation. In other words, each successive event that takes place in the expression of a gene is a potential control point for gene expression.

We begin by discussing gene regulation in eukaryotes, and then turn to gene regulation in prokaryotes and viruses. All life, from the simplest to the most complex, requires gene regulation. Gene regulation relies on similar processes in all organisms because all life shares common ancestry. Nevertheless, certain features of eukaryotes—the packaging of DNA into chromosomes, mRNA processing, and the separation in space of transcription and translation—provide additional levels of gene regulation in eukaryotes that are not possible in prokaryotes.

# 18.1 CHROMATIN TO MESSENGER RNA IN EUKARYOTES

Gene regulation in multicellular eukaryotes leads to cell specialization: different types of cell express different genes. The human body contains about 200 major cell types, and although for the most part they share the same genome, they look and function differently from one another because each type of cell expresses different sets of genes. For example, the insulin needed to regulate sugar levels in the blood is produced only by small patches of cells in the pancreas. Every cell in the body contains the genes that encode insulin, but only in these patches of pancreatic cells are they expressed. Insufficient insulin is one factor that causes type 2 diabetes, a complex trait in which levels of blood glucose are higher than normal. In this section, we explore gene regulation as it occurs in eukaryotic cells, focusing on regulation at the level of DNA, chromatin, and mRNA.

**Gene expression can be influenced by chemical modification of DNA or histones.**

**Fig. 18.1** shows the major places where gene regulation in eukaryotes can take place. The first level of control is at the chromosome, even before transcription takes place. The manner in which DNA is packaged in the nucleus in eukaryotes provides an important opportunity for regulating gene expression. Regulation at this level of

gene expression is determined, in part, by whether the proteins necessary for transcription can gain physical access to the genes they transcribe.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 18.1 Levels of gene regulation in eukaryotes.

DNA in eukaryotes is packaged as **chromatin**, a complex of DNA, RNA, and proteins that gives chromosomes their structure ([Chapter 13](#)). When chromatin is in its coiled state, the DNA is not accessible to the proteins that carry out transcription. The chromatin must loosen to allow space for transcriptional enzymes and proteins to work. This is accomplished through **chromatin remodeling**, in which the nucleosomes are repositioned to expose different stretches of DNA to the nuclear environment.

One way in which chromatin is remodeled is by chemical modification of the histones around which DNA is wound ([Fig. 18.2](#)). Modification usually occurs on **histone tails**, which are strings of amino acids that protrude from the histone proteins in the nucleosome. Individual amino acids in the tails can be modified by the addition (or later removal) of different chemical groups, including methyl groups ( $\text{—CH}_3$ ) and acetyl groups ( $\text{—COCH}_3$ ). Most often, methylation or acetylation occurs on the lysine residues of the histone tails. Some of these modifications tend to activate transcription and others to repress transcription. The pattern of modifications of the histone tails constitutes a **histone code** that affects chromatin structure and gene transcription. Modification of histones takes place at key times in development to ensure that the proper genes are turned on or off, as well as in response to environmental cues.

FIG. 18.2 Histone modifications. Typical modifications of the amino acid lysine observed in the histone tails of nucleosomes include addition of a methyl group (Me), addition of three methyl groups (Me<sub>3</sub>), and acetylation (Ac).

In many eukaryotic organisms, gene expression is also affected by chemical modification of certain bases in the DNA, the most common of which is the addition of a methyl group to the base cytosine ([Fig. 18.3](#)). DNA methylation recruits proteins that lead to changes in chromatin structure, histone modification, and nucleosome positioning that restrict access of transcription factors to promoters. Methylation of cytosines often occurs in [CpG islands](#), which are clusters of adjacent CG nucleotides located in or near the promoter of a gene. Heavy cytosine methylation is associated with transcriptional repression of the gene near the CpG island. The methylation state of a CpG island can change over time or in response to environmental signals, providing a

way to turn genes on or off. As a defense mechanism, cells sometimes heavily methylate CpG islands of transposable elements or viral DNA sequences that are integrated into the genome, thus preventing the expression of genes in the foreign DNA ([Chapter 14](#)).

FIG. 18.3 Methylation states of CpG islands in or near the promoter of a gene.

Together, the modification of cytosine bases, changes to histones, and alterations in chromatin structure are often termed **epigenetic**, from the Greek *epi* (“over and above”) and “genetic” (“inheritance”). That is, epigenetic mechanisms of gene regulation typically involve changes not to the DNA sequence itself but to the manner in which the DNA is packaged. Epigenetic modifications can, in some cases, affect gene expression. They can be inherited through mitotic cell divisions, just as genes are, but are often reversible and responsive to changes in the environment. Furthermore, epigenetic modifications present in

sperm or eggs are sometimes transmitted from parent to offspring, meaning that these chemical modifications can be inherited.

In humans and other mammals, about 100 genes are repressed by chemical modifications such as DNA methylation in the germ line in a sex-specific manner. This sex-specific silencing of gene expression is known as **imprinting**. For some genes, the allele of the gene inherited from the mother is imprinted and therefore silenced, so only the allele inherited from the father is expressed. For other imprinted genes, the allele of the gene inherited from the father is imprinted and therefore silenced, so only the allele inherited from the mother is expressed. The imprinting persists in somatic cells throughout the lifetime of the individual, but it is reset in its germ line according to the individual's sex.

Some of the genes that are imprinted affect the growth rate of the embryo. For example, in matings between lions and tigers that take place in captivity, the offspring of a male tiger with a female lion (a “tigon”) is about the same size as its parents, whereas the offspring of a male lion and a female tiger (a “liger”) is a giant cat—the largest of any big cat that exists. Much of the size difference between a liger and a tigon is thought to result from whether genes for rapid embryonic growth that are subject to imprinting are inherited from the mother or the father.

## Gene expression can be regulated at the level of an entire chromosome.

A striking example of an epigenetic form of gene regulation is the

manner in which mammals equalize the expression of *X*-linked genes in *XX* females and *XY* males. For most genes, a direct relation exists between the number of copies of the gene (the gene dosage) and the level of expression of the gene. An increase in gene dosage increases the level of expression because each copy of the gene is regulated independently of other copies. For example, as we saw in [Chapter 14](#), the presence of an extra copy of most human chromosomes results in spontaneous abortion because of the increase in the expression of the genes in that chromosome.

*XX* females have twice as many *X* chromosomes as *XY* males. For genes located in the *X* chromosome, the dosage of genes is twice as great in females as it is in males. However, the level of expression of *X*-linked genes is about the same in both sexes. These observations imply that the regulation of genes in the *X* chromosome is different in females and in males. This differential regulation is called [dosage compensation](#).

Different species have evolved different mechanisms of dosage compensation. In the fruit fly *Drosophila*, males double the transcription of the single *X* chromosome to achieve equal expression compared to the two *X* chromosomes in females. In the nematode worm *Caenorhabditis*, transcription of both *X* chromosomes in females is decreased to one-half the level of the single *X* chromosome in males. In mammals, including humans, dosage compensation occurs through the inactivation of one *X* chromosome in each cell in females. This process, known as [X-inactivation](#), was first proposed by Mary F. Lyon in the early 1960s.

Soon after a fertilized egg with two  $X$  chromosomes implants in the mother's uterine wall (after several cell divisions have occurred), one  $X$  chromosome at random is inactivated ([Fig. 18.4](#)). In [Fig. 18.4a](#), the inactive  $X$  chromosome is shown in gray. The inactive state persists through cell division, so in each cell lineage, the same  $X$  chromosome that was originally inactivated remains inactive. The result is that a normal female is a mosaic, or patchwork, of tissue. In some patches, the genes in the maternal  $X$  chromosome are expressed (and the paternal  $X$  chromosome is inactivated), whereas in other patches, the genes in the paternal  $X$  chromosome are expressed (and the maternal  $X$  chromosome is inactivated). The term “inactive  $X$  chromosome” is a slight exaggeration because a substantial number of genes are still transcribed, although usually at a low level.

**FIG. 18.4**  $X$ -inactivation in female mammals.  $X$ -inactivation equalizes the expression of most genes in the  $X$  chromosome between  $XX$  females and  $XY$  males.

As one argument for her  $X$ -inactivation hypothesis, Lyon called

attention to calico cats, which are nearly always female ([Fig. 18.4b](#)). In calico cats, the orange and black fur colors are due to different alleles of a single gene in the *X* chromosome. In a heterozygous female, *X*-inactivation predicts discrete patches of orange and black, and this is exactly what is observed. (The white patches on a calico cat are due to an autosomal gene.)

How does *X*-inactivation work? Some of the details are still unknown, but the main features of the process are shown in [Fig. 18.5](#). A key player is a small region in the *X* chromosome called the *X*-chromosome inactivation center (*XIC*), which contains a gene called *Xist* (*X*-inactivation specific transcript). The *Xist* gene is normally transcribed at a very low level, and the RNA is unstable. However, in an *X* chromosome that is about to become inactive, *Xist* transcription markedly increases. The transcript undergoes RNA splicing, but it does not encode a protein. Therefore, *Xist* RNA is an example of a noncoding RNA ([Chapter 3](#)). Instead of being translated, the processed *Xist* RNA coats the *XIC* region, and as it accumulates, the coating spreads outward from the *XIC* until the entire chromosome is coated with *Xist* RNA. The presence of *Xist* RNA along the chromosome recruits factors that promote DNA methylation, histone modification, and other changes associated with transcriptional repression.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 18.5 The role of *Xist* in X-inactivation. The *Xist* transcript is a noncoding RNA that is expressed from the inactive X chromosome and coats the entire chromosome, leading to inactivation of most of the genes in the chromosome.

The *Xist* gene is both necessary and sufficient for X-inactivation: if it is deleted, X-inactivation does not occur; if it is inserted into another chromosome, it inactivates that chromosome. Using recombinant DNA techniques such as those described in [Chapter 12](#), researchers were able to insert *Xist* into one of the three copies of chromosome 21 present in cells taken from a patient with Down syndrome. Remarkably, *Xist* in its new location in chromosome 21 produced an RNA transcript that coated that copy of chromosome 21 and repressed most of the transcription of its genes! Whether all genes in

chromosome 21 are repressed, and whether they are as fully repressed as those in the inactive *X* chromosome, are questions that are still being investigated, but this finding raises clear (but still speculative) ideas about how *Xist* might be used as a potential treatment for Down syndrome and various other chromosomal disorders.

## Transcription is a key control point in gene expression.

Although access to DNA is necessary for transcription, it is not sufficient. The molecular machinery that actually carries out transcription is also required once the template DNA is made accessible through chromatin remodeling and histone modification. The mechanisms that regulate whether or not transcription occurs are known collectively as **transcriptional regulation** (see [Fig. 18.1b](#)).

Transcriptional regulation in eukaryotic cells requires the coordinated action of many proteins that interact with one another and with DNA sequences near the gene. Let's first review the basic process of transcription in eukaryotes ([Chapter 3](#)). Initially, an important group of proteins called **general transcription factors** are recruited to the gene's promoter, which is the region of a gene where transcription is initiated. The transcription factors are brought there by one of the proteins that bind to a short sequence in the promoter called the TATA box, which is usually situated 25–30 nucleotides upstream of the nucleotide site where transcription begins. Once bound to the promoter, the transcription factors recruit the components of the **RNA polymerase complex**, which is the enzyme complex that synthesizes the RNA transcript complementary to the template strand of DNA.

Where in the many steps of transcription initiation does regulation occur? Transcription initiation can be regulated at the level of recruitment of the general transcription factors and components of the RNA polymerase complex. Recruitment of these elements is controlled by proteins called **regulatory transcription factors**. Some regulatory transcription factors recruit chromatin remodeling proteins that allow physical access to a gene. Other regulatory transcription factors have two binding sites, one of which binds with a particular DNA sequence in or near a gene known as an **enhancer** and the other of which recruits one or more general transcription factors to the promoter region (**Fig. 18.6**). The general transcription factors then recruit the RNA polymerase complex, and transcription can begin (**Chapter 3**). Transcription does not occur if the regulatory transcription factors fail to recruit the general transcription factors to the gene.

FIG. 18.6 Protein–DNA and protein–protein interactions in the eukaryotic transcription complex.

Hundreds of different regulatory transcription factors control the transcription of thousands of genes. Some bind with enhancers and stimulate transcription; others bind with DNA sequences known as **silencers** and repress transcription. Enhancers and silencers are often in or near the genes they regulate, but, in some cases, they may be many thousands of nucleotides distant from the genes. A typical gene may be regulated by multiple enhancers and silencers of different types, each with one or more regulatory transcription factors that can bind with it. Transcription takes place only when the proper combination of regulatory transcription factors is present in the same cell, as shown in **Fig. 18.6**. Transcription of a gene with multiple silencers and enhancers depends on the presence of a particular combination of regulatory transcription factors, so this type of regulation is called **combinatorial control**.

## RNA processing is also important in gene regulation.

A great deal happens in the nucleus after transcription takes place. The initial transcript, called the **primary transcript**, undergoes several modifications, which are collectively called **RNA processing** (**Chapter 3**) and include the addition of a nucleotide cap to the 5' end and a string of tens to hundreds of adenosine nucleotides to the 3' end to form the poly(A) tail. These modifications are necessary for the RNA molecule to be transported to the cytoplasm and recognized by the translational

machinery. The poly(A) tail also helps to determine how long the RNA will persist in the cytoplasm before being degraded. Therefore, RNA processing is an important point where gene regulation can occur (see [Fig. 18.1c](#)).

In eukaryotes, the primary transcript of many protein-coding genes is far longer than the mRNA ultimately used in protein synthesis. The long primary transcript consists of regions that are retained in the mRNA (the [exons](#)) interspersed with regions that are excised and degraded (the [introns](#)). The introns are excised during [RNA splicing](#) ([Chapter 3](#)). The exons are joined together in their original linear order to form the processed mRNA.

RNA splicing provides an opportunity for regulating gene expression because the same primary transcript can be spliced in different ways to yield different proteins in a process called [alternative splicing](#). This process takes place because what the spliceosome—the splicing machinery—recognizes as an exon in some primary transcripts, it also recognizes as part of an intron in other primary transcripts. The alternative-splice forms may be produced in the same cells or in different types of cell. Alternative splicing accounts, in part, for the observation that we produce many more proteins than our total number of genes. By some estimates, over 90% of human genes undergo alternative splicing.

[Fig. 18.7](#) shows the primary transcript of a gene encoding an insulin receptor found in humans and other mammals. During RNA splicing in liver cells, exon 11 is included in the mRNA, and the insulin receptor

produced from this mRNA has low affinity for insulin. In contrast, in cells of skeletal muscle, the 36 nucleotides of exon 11 are spliced out of the primary transcript along with the flanking introns. The resulting protein is 12 amino acids shorter, and this form of the insulin receptor has a high affinity for insulin. The different forms of the protein are important: the higher sensitivity of muscle cells to insulin enables them to absorb enough glucose to fulfill their energy needs.

FIG. 18.7 Alternative splicing of a mammalian insulin-receptor transcript. Alternative splicing generates different processed mRNAs and different proteins from the same primary transcript.

Some RNA molecules can become a substrate for enzymes that modify particular bases in the RNA, thus changing its sequence and what it codes for. This process is known as **RNA editing** (Fig. 18.8). One type of editing enzyme removes the amino group ( $-\text{NH}_2$ ) from

adenosine and converts it to inosine, which in translation functions like guanosine ([Fig. 18.8a](#)). Another enzyme removes the amino group from cytosine and converts it to uracil ([Fig. 18.8b](#)). In the human genome, hundreds if not thousands of transcripts undergo RNA editing. In many cases, not all copies of the transcript are edited, and some copies may be edited more extensively than others. The result is that transcripts from the same gene can produce multiple types of proteins, even in a single cell.

Transcripts from the same gene may undergo different editing in different cell types. An example of tissue-specific RNA editing is shown in [Fig. 18.9](#). The mRNA fragments show part of the coding sequence for apolipoprotein B. The unedited mRNA in the liver ([Fig. 18.9a](#)) is translated into a protein that transports cholesterol in the

blood. In contrast, RNA editing of the message occurs in the intestine ([Fig. 18.9b](#)). The cytosine nucleotide in codon 2153 is edited to uracil. The edited codon is UAA, which is a stop codon. Translation therefore terminates at this point, releasing a protein only about half as long as the liver form. This shorter form of the protein helps the cells of the intestine absorb lipids from the foods we eat.

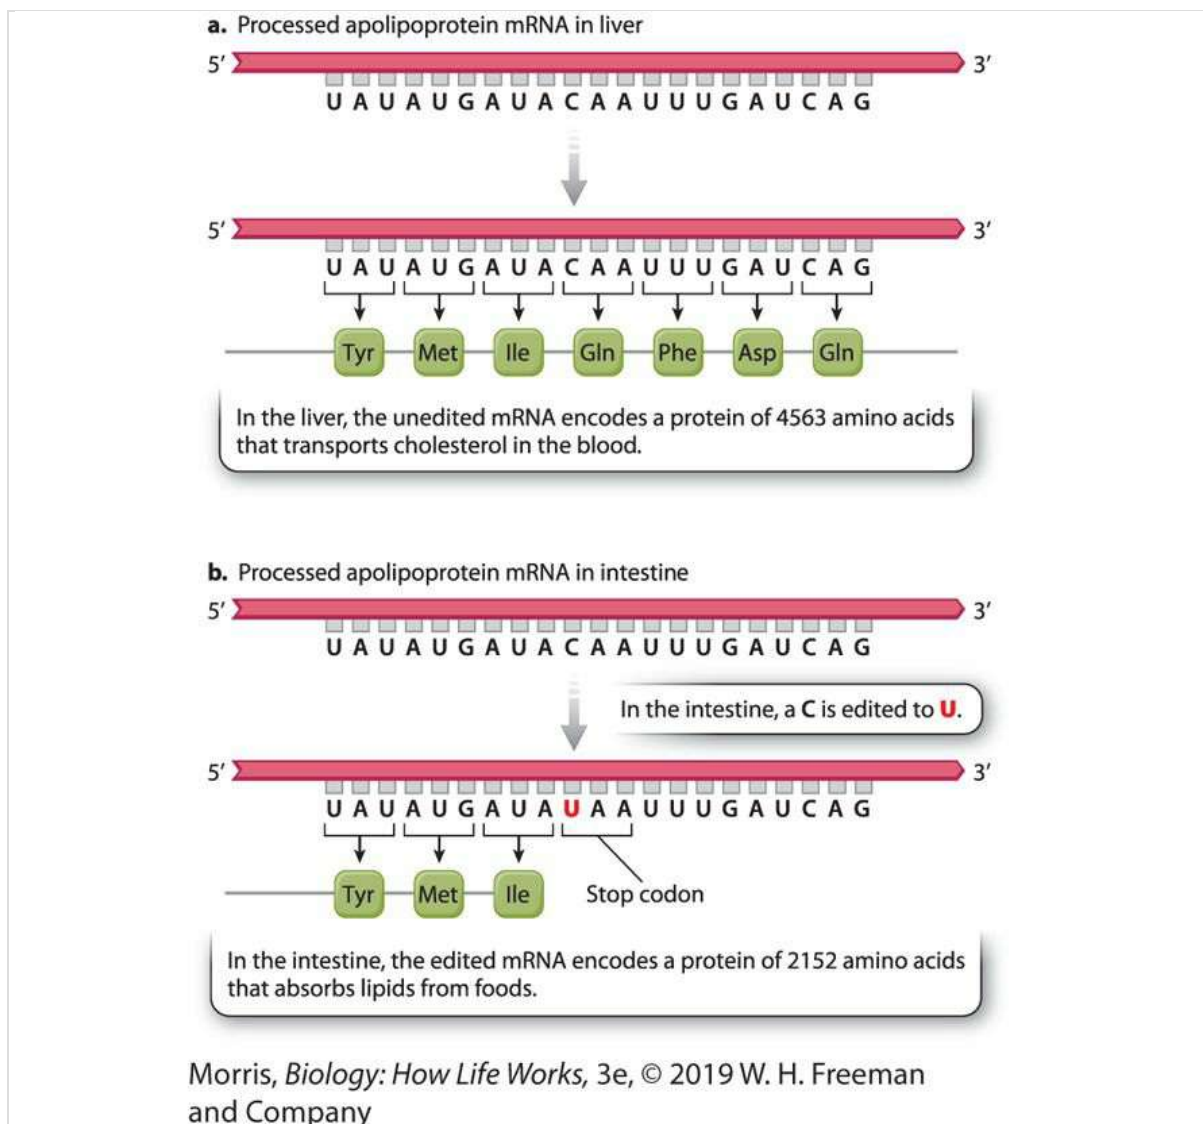

FIG. 18.9 Tissue-specific RNA editing of the human apolipoprotein B transcript. Different RNA editing in (a) the liver and (b) the intestine results in proteins with different functions.

### Self-Assessment Questions

1. What is the difference between gene expression and gene regulation?
2. What is meant by different “levels” of gene regulation?
3. How can DNA bases and chromatin can be modified to regulate gene expression? Does this modification result in increased or decreased gene expression?
4. How does *X*-inactivation in female mammals result in patchy coat colors in calico cats?
5. How can one protein-coding gene code for more than one polypeptide chain?

## 18.2 MESSENGER RNA TO PHENOTYPE IN EUKARYOTES

In eukaryotes, a processed mRNA must exit the nucleus before the translation step of gene expression can occur. The mRNA migrates to the cytoplasm through one of a few thousand nuclear pores, which are large protein complexes that span both layers of the nuclear envelope and regulate the flow of macromolecules in and out of the nucleus ([Chapter 5](#)). Once the mRNA is in the cytoplasm, there are multiple opportunities for gene regulation at the levels of mRNA stability, translation, and protein activity (see [Figs. 18.1d–18.1f](#)).

### Small regulatory RNAs inhibit translation or promote mRNA degradation.

Regulatory RNA molecules known as [small regulatory RNAs](#) are among the most exciting recent discoveries in gene regulation. They are of exceptional interest to biologists and drug researchers because their small size allows easy synthesis in the laboratory, and researchers can design their sequences to target transcripts of interest.

Two important types of small regulatory RNAs are known as [siRNA \(small interfering RNA\)](#) and [miRNA \(microRNA\)](#). Although they have somewhat different functions, they share similarities in how they are produced ([Fig. 18.10](#)). Both types of small regulatory RNA are transcribed from DNA and form hairpin, or stem-and-loop,

structures in the nucleus, which are stabilized by base pairing in the stem. Enzymes in the cytoplasm specifically recognize these structures and cleave the stem from the hairpin, and then further cut the stem into small, double-stranded fragments that are 20–25 base pairs in length.

FIG. 18.10 Production of small regulatory RNAs and an overview of their functions.

One of the two strands from each RNA fragment is incorporated into a protein complex known as **RISC (RNA-induced silencing complex)**. The small, single-stranded RNA targets the RISC to specific RNA molecules by base pairing with short regions in the target. Depending on the type of small regulatory RNA, the RNA sequence in

the RISC, and the particular type of RISC, the small regulatory RNA may result in chromatin remodeling, degradation of RNA transcripts, or inhibition of mRNA translation ([Fig. 18.10](#)).

Regulation by small regulatory RNAs is widespread in eukaryotes, and it is thought to have evolved originally as a defense against viruses and transposable elements. These molecules also evolved to have important regulatory roles in their own right. Human chromosomes are thought to encode about 1000 microRNAs, each of which can target tens or hundreds of mRNA molecules. Half or more of human proteins may have their synthesis regulated, in part, by such small regulatory RNAs.

## Translational regulation controls the rate, timing, and location of protein synthesis.

Translation of mRNA into protein provides another level of control of gene expression. [Fig. 18.11](#) shows the structure of a hypothetical mRNA molecule in a eukaryotic cell and highlights some of the features that help regulate its translation ([Chapter 4](#)). Not all mRNA molecules have all the features shown, but almost all mRNA molecules have a 5' cap, a 5' untranslated region (5' UTR), an open reading frame (ORF) containing the codons that determine the amino acid sequence of the protein, a 3' untranslated region (3' UTR), and a poly(A) tail. The 5' UTR and 3' UTR may contain regions that bind with regulatory proteins. These RNA-binding proteins help control mRNA translation and degradation. The UTRs may also contain binding sites for small

regulatory RNAs. During development, as we will see in [Chapter 19](#), some RNA-binding proteins interact with molecular motors that transport the mRNA to particular regions of the cell. In other cases, the proteins are only in particular locations in the cell and repress translation of the mRNAs that are transported there and to which they bind. By either transport or repression, these proteins cause the mRNA to be translated only in certain places in the cell.

FIG. 18.11 Some features of mRNA that affect gene expression. These include the 5' cap, 5' untranslated region (5' UTR), open reading frame (ORF), 3' untranslated region (3' UTR), and poly(A) tail.

The cap structure is one of the main recognition signals for translation initiation, which requires the coordinated action of about 25 proteins. These proteins are present in most cells in limited amounts. Therefore, at any given time, while some mRNAs from a gene are being translated, other mRNAs transcribed from the same gene may not have a translation initiation complex assembled.

The 3' UTR and the poly(A) tail are also important in translation

initiation. The efficiency of translation initiation is greatly increased by physical contact between a protein that binds the poly(A) tail and one that binds the 5' cap. The physical contact creates a loop in the mRNA, bringing the 3' end of the mRNA into proximity with the start site for translation. In fact, most mRNA sequences that regulate translation are present in the 3' UTR.

Although translation initiation is the principal mode of translational regulation, not all mRNA molecules are equally accessible to translation. Among the key variables are the secondary (folded) structure of the 5' UTR, the distance from the 5' cap to the AUG initiation codon, and the sequences flanking the AUG initiation codon.

## Protein structure and chemical modification modulate protein effects on phenotype.

Once translation is completed, the resulting protein can alter the phenotype of the cell or organism by affecting metabolism, signaling, gene expression, or cell structure. After translation, proteins are modified in multiple ways that regulate their structure and function. Collectively, these processes are called **posttranslational modification** (see [Fig. 18.1e](#)). Regulation at this level is essential because some proteins are downright dangerous. For example, proteases, such as the digestive enzyme trypsin, must be kept inactive until they are secreted out of the cell. If they were not kept inactive, their activity would kill the cell. These types of protein are often controlled by being translated in inactive forms that are made active by

modification after secretion.

Folding and acquiring stability are key control points for some proteins ([Chapter 4](#)). Although many proteins fold properly as they come off the ribosome, others require help from proteins called chaperones that act as folding facilitators. Correct folding is important because improperly folded proteins may bind together to form aggregates that are destructive to cell function. Many diseases are associated with protein aggregates, including Alzheimer's disease, Huntington's disease, and the human counterpart of mad cow disease.

Posttranslational modification also helps regulate protein activity. Many proteins are modified by the addition of one or more sugar molecules to the side chains of some amino acids. This modification can alter the protein's folding and stability, or target the molecule to particular cellular compartments. Reversible addition of a phosphate group to the side chains of amino acids such as serine, threonine, or tyrosine is a key regulator of protein activity ([Chapter 9](#)). Introduction of the negatively charged phosphate group alters the conformation of the protein, in some cases switching it from an inactive state to an active state and in other cases the reverse. Because the function of a protein molecule results from its shape and charge ([Chapter 4](#)), a change in protein conformation affects protein function.

Marking proteins for enzymatic destruction by the addition of chemical groups after translation is also important in controlling their activity. For example, we have seen how the destruction of successive waves of cyclin proteins helps move the cell through its division cycle

([Chapter 11](#)).

### CASE 3 YOUR PERSONAL GENOME: YOU, FROM A TO

T

## How do lifestyle choices affect expression of your personal genome?

If you examine [Fig. 18.1](#) as a whole and consider the DNA sequence shown as your personal genome, the situation looks pretty grim. You might be led to believe that genes dictate everything, and that biology is destiny. However, if you focus on the lower levels of regulation in [Fig. 18.1](#), a different picture emerges. The picture is different because much of the regulation that occurs after transcription (regulation of mRNA stability, regulation of translation, posttranslational modifications) is determined by the physiological state of your cells, which, in turn, is strongly influenced by your lifestyle choices. For example, your cells can synthesize 12 of the amino acids in proteins, but if any of these is present in sufficient amounts in your diet, it is absorbed during digestion and not synthesized. The amino acid you ingest blocks the amino acid-synthesizing pathway through feedback effects.

The effect of an intervention in gene expression—genetic or environmental—at any given level can affect regulatory processes at both higher and lower levels. This cascade of regulatory effects in both directions can occur because the expression of any gene is regulated at

multiple levels, and because much feedback and signaling occurs back and forth between nucleus and cytoplasm. It is because of these feedback and signaling mechanisms that the effects of lifestyle choices can be propagated up the regulatory hierarchy. For example, it has been shown that dietary intake of fats and cholesterol affects not only the activity of enzymes directly involved in the metabolism of fats and cholesterol, but also the levels of transcription of the genes encoding these enzymes by affecting the activity of their regulatory transcription factors. Similarly, lifestyles that combine balanced diets with exercise and stress relief have been shown to increase transcription of genes whose products prevent cellular dysfunction and decrease transcription of genes whose products promote disease.

The interplay of different levels of gene regulation with environmental factors underlies many complex traits of the type discussed in [Chapter 17](#), which are affected by multiple genes and by multiple environmental factors as well as by genotype-by-environment interaction. For example, both genetic and environmental risk factors exist for breast and ovarian cancers, as we have seen. Simple Mendelian traits caused by mutations in single genes, such as cystic fibrosis and alpha-1 antitrypsin ( $\alpha$ -1AT) deficiency ([Chapter 16](#)), are less responsive to lifestyle choices. Even in these cases, however, lifestyle matters. For example, people with  $\alpha$ -1AT deficiency should not smoke tobacco and should avoid environments with low air quality.

#### Self-Assessment Questions

6. How do small regulatory RNAs differ from mRNA?

7. What are three ways in which gene expression can be influenced after mRNA is processed and leaves the nucleus?

---

## 18.3 TRANSCRIPTIONAL REGULATION IN PROKARYOTES

The central message of [Fig. 18.1](#) is that the regulation of gene expression occurs through a hierarchy of regulatory mechanisms acting at different levels (and usually at multiple levels) from DNA to protein. Gene regulation in prokaryotes is simpler than gene regulation in eukaryotes because DNA is not packaged into nucleosomes, mRNA is not processed, and transcription and translation are not separated by a nuclear envelope. In prokaryotes, expression of a protein-coding gene entails transcription of the gene into mRNA and translation of the mRNA into protein. Each of these levels of gene expression is subject to regulation.

Because gene regulation in prokaryotes is simpler than gene regulation in eukaryotes, prokaryotes have served as model organisms for our understanding of how genes are turned on and off. In this section, we consider in more detail how gene expression is regulated at the level of transcription in bacteria and in viruses that infect bacteria. We focus on two well-studied systems: (1) the regulation of genes in the intestinal bacterium *Escherichia coli* (*E. coli*) that allows lactose-metabolizing proteins to be produced only when lactose is present in the environment and only when it is the best nutrient available, and (2) the regulation of genes in a virus that infects *E. coli* that controls whether the virus integrates its DNA into the bacterial host or lyses (breaks open) the cell. In both cases, specific genes are turned on and

off in response to environmental conditions.

## Transcriptional regulation can be positive or negative.

In both eukaryotes and prokaryotes, transcription can be positively or negatively regulated. In [positive regulation](#), a regulatory molecule (usually a protein) must bind to the DNA at a site near the gene in order for transcription to take place. In [negative regulation](#), a regulatory molecule (again, usually a protein) must bind to the DNA at a site near the gene in order for transcription to be prevented. Most promoters contain one or more short sequences that help recruit the proteins needed for transcription when transcription of the gene is activated. In eukaryotes, many promoters contain the sequence 5'-TATAAA-3' (or some variant of this sequence) about 25–35 base pairs upstream from the transcription start site, which helps recruit the proteins needed for transcription. Many prokaryotic promoters contain a pair of such regulatory sequences located about 10 and 35 base pairs upstream of the transcription start site. These promoter sequences are called the –10 and –35 sequence motifs.

[Fig. 18.12](#) illustrates positive regulation. The main players are DNA, the RNA polymerase complex, and a regulatory protein called a transcriptional [activator](#). The DNA contains two important binding sites: one for the activator protein, and one for the RNA polymerase complex. As shown in [Fig. 18.12a](#), when the activator protein is present in a state that can interact with its binding site in the DNA, the RNA polymerase complex is recruited to the promoter of the gene and transcription takes place. When the activator is not present or is not

able to bind with the DNA ([Fig. 18.12b](#)), the RNA polymerase is not recruited to the promoter and transcription does not occur. The binding site for the activator may be upstream of the promoter, as shown in the figure, be downstream of the promoter, or even overlap the promoter.

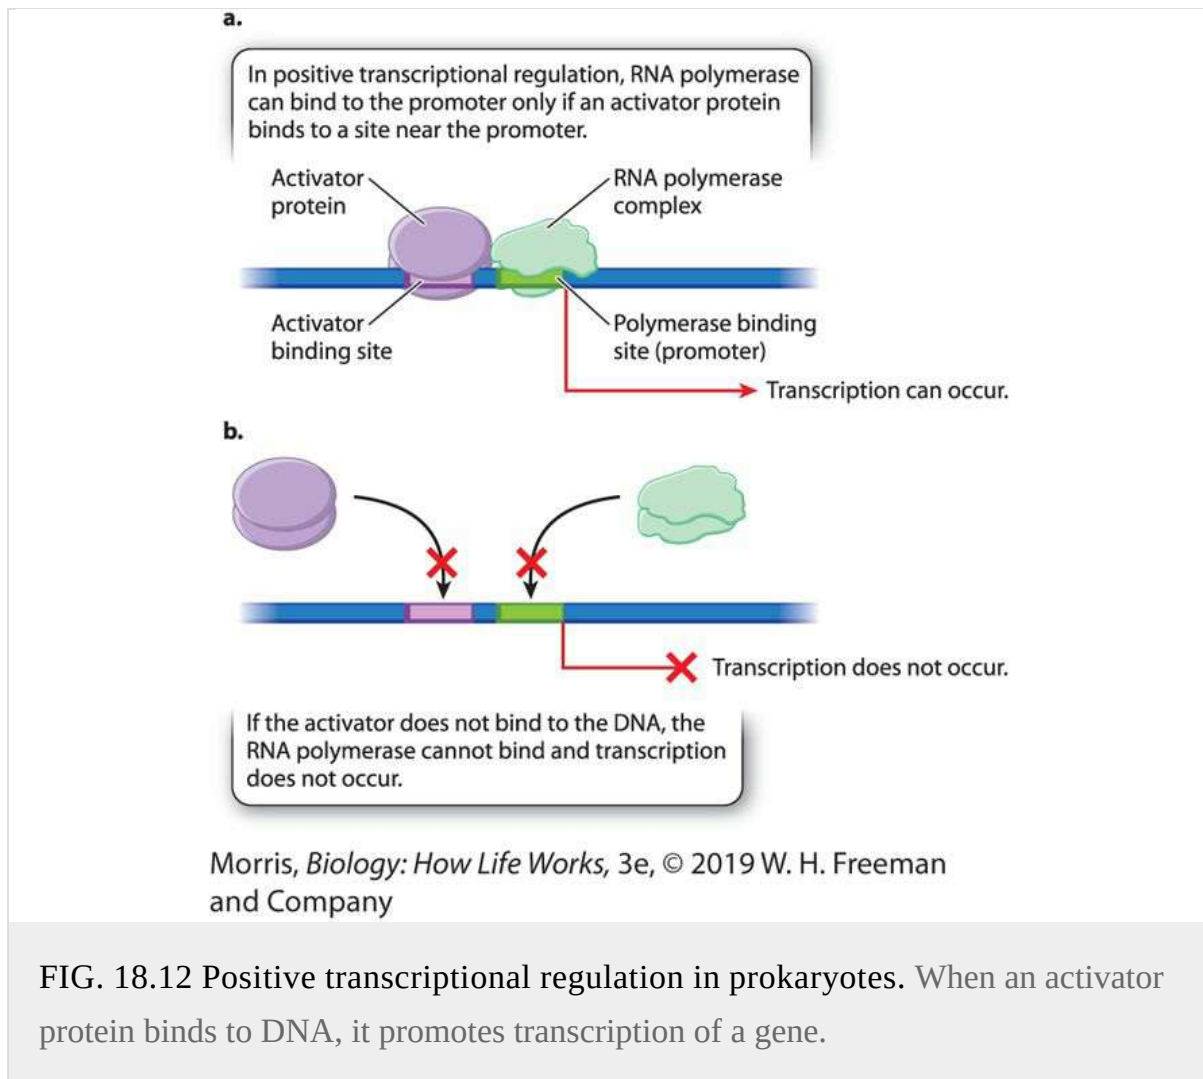

FIG. 18.12 Positive transcriptional regulation in prokaryotes. When an activator protein binds to DNA, it promotes transcription of a gene.

Sometimes, the activator protein combines with a small molecule in the cell and undergoes a change in shape that alters its binding affinity for DNA. The change in shape is an example of an [allosteric effect](#) ([Chapter 6](#)). In some cases, the activator on its own cannot bind with DNA, but combining with the small molecule changes its shape so that it can bind with particular sequences in the DNA. Therefore, the

presence of the small molecule in the cell results in transcription of the gene. Genes subject to this type of positive control typically encode proteins that are needed only when the small molecule is present in the cell. For example, in *E. coli*, the genes for the breakdown of the sugar arabinose are normally repressed in the absence of the sugar because a regulatory protein binds the DNA in such a way as to prevent transcription. In the presence of arabinose, however, the shape of the protein is altered so that it binds a different site in the DNA, allowing transcription of the genes. For other genes, activator proteins can bind DNA only when a small molecule is absent from the cell. These genes typically encode proteins needed for synthesis of the small molecule. In *E. coli*, the genes for synthesis of the amino acid cysteine are regulated in this fashion.

**Fig. 18.13** illustrates negative regulation. In this case, the DNA in its native state can recruit the RNA polymerase complex, and transcription takes place at a constant rate unless something turns it off (**Fig. 18.13a**). Binding with a protein called a **repressor** turns off transcription (**Fig. 18.13b**). Again, the binding site for the repressor can be upstream of the promoter, downstream of the promoter, or overlapping with the promoter.

FIG. 18.13 Negative transcriptional regulation in prokaryotes. When a repressor protein binds to DNA, it prevents transcription of a gene.

As with positive control, the ability of the repressor to bind DNA is often determined by an allosteric interaction with a small molecule. A small molecule that interacts with the repressor and prevents it from binding DNA and blocking transcription is called an **inducer**. In the next section, we will look closely at the regulation of genes for the breakdown of the sugar lactose in *E. coli*, and we will see that a derivative of lactose binds to and inhibits the repressor and is therefore an inducer of these genes.

In other cases, the small molecule changes the conformation of the

repressor so that it can bind to the repressor binding site and inhibit transcription. Genes regulated in this way are often needed for synthesis of the small molecule. In *E. coli*, for example, the genes for the synthesis of the amino acid tryptophan are negatively regulated by tryptophan. When tryptophan is present in sufficient amounts, it binds with a regulatory protein to form the functional repressor, and transcription of the genes does not occur. When the level of tryptophan drops too low to form the repressor, transcription of the genes is initiated.

## Lactose utilization in *E. coli* is the pioneering example of transcriptional regulation.

The principle that the product of one gene can regulate transcription of other genes was first discovered in the 1960s by François Jacob and Jacques Monod, who studied how the bacterium *E. coli* regulates production of the proteins needed for utilization of the sugar lactose. Lactose consists of one molecule each of the sugars glucose and galactose, which are covalently linked by a  $\beta$ -(beta-)galactoside bond. An enzyme called  $\beta$ -galactosidase cleaves lactose, releasing glucose and galactose. Both molecules can then be broken down and used as a source of carbon and energy ([Chapter 7](#)).

Jacob and Monod began their research with the observation that active  $\beta$ -galactosidase enzyme is observed in cells only in the presence of lactose or certain molecules that are chemically similar to lactose. Why is this so? [Fig. 18.14](#) describes and tests two hypotheses. One is

that lactose stabilizes an unstable form of  $\beta$ -galactosidase that is produced by all cells all the time, thus activating the enzyme. The other is that lactose leads to the expression of the gene for  $\beta$ -galactosidase. The experiment shown in [Fig. 18.14](#) supported the hypothesis that lactose turns on the  $\beta$ -galactosidase gene. The way in which lactose activates expression of the  $\beta$ -galactosidase gene was the subject of additional experiments. These Nobel Prize winning follow-up studies of Jacob and Monod gave the first demonstrated example of transcriptional gene regulation.

#### HOW DO WE KNOW?

### FIG. 18.14

## How does lactose lead to the production of active $\beta$ -galactosidase enzyme?

#### BACKGROUND

Active  $\beta$ -galactosidase enzyme is observed only in *E. coli* cells that are growing in the presence of lactose.

#### HYPOTHESIS

One hypothesis is that the enzyme is always being produced, but is produced in an unstable form that breaks down rapidly in the absence of lactose. An alternative hypothesis is that the enzyme is stable, but is produced only in the presence of lactose.

#### EXPERIMENT

French biologists François Jacob and Jacques Monod exposed a culture of growing cells to lactose and later removed the lactose. The researchers measured the amount of  $\beta$ -galactosidase present in the culture during the exposure to lactose and its removal.

#### RESULTS

Almost immediately upon addition of lactose,  $\beta$ -galactosidase began to accumulate, and its amount steadily increased. When lactose was removed, the enzyme did not disappear immediately (as would be the case if it were unstable, as predicted by the first hypothesis). Instead, the amount of enzyme remained the same as when lactose was present. This result is expected only if  $\beta$ -galactosidase is a stable enzyme that is synthesized when lactose is added and stops being synthesized when lactose is removed (as predicted by the second hypothesis).

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## CONCLUSION

Synthesis of  $\beta$ -galactosidase turns on when lactose is added and turns off when lactose is removed. These results support the second hypothesis, which asserts that the enzyme is stable but is produced only in the presence of lactose.

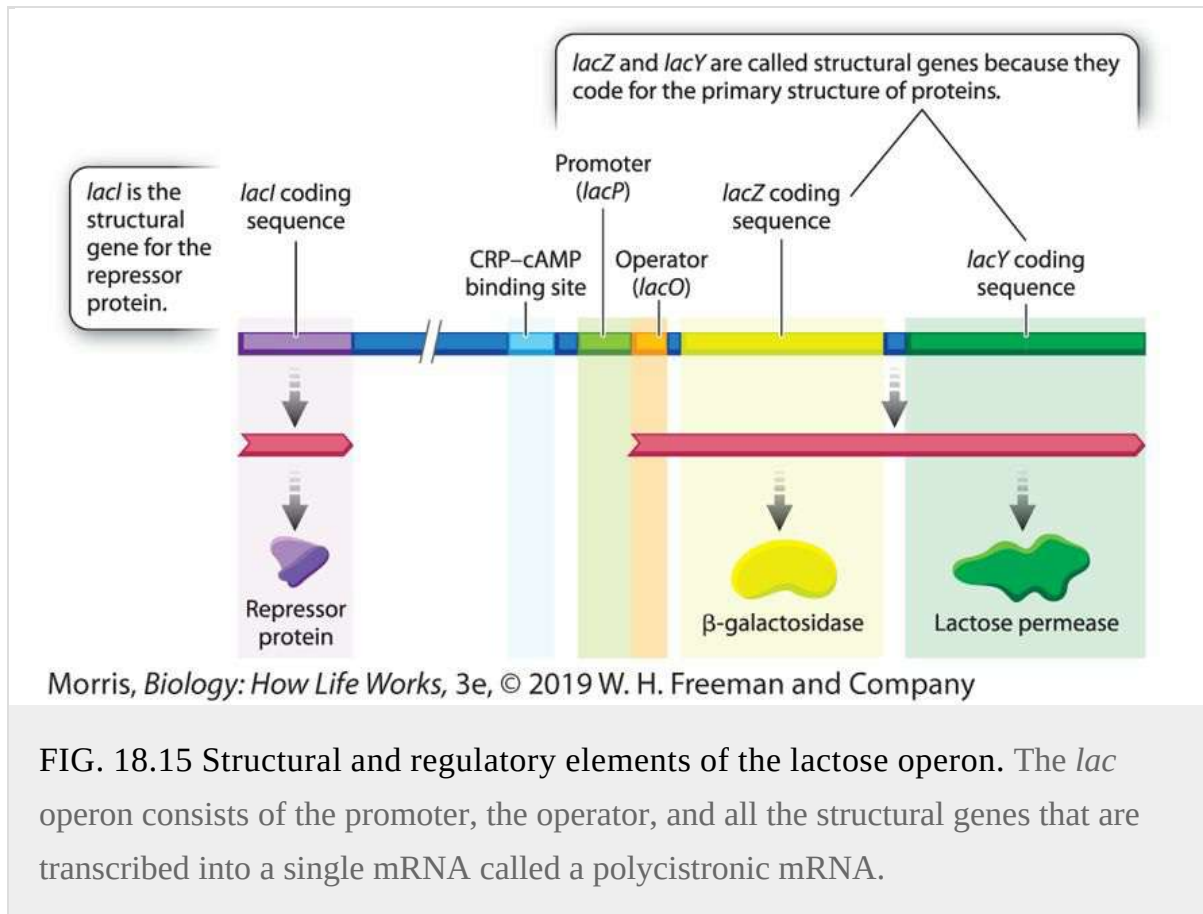

## FOLLOW-UP WORK

These pioneering experiments ultimately led to the discovery of the lactose operon and the mechanism of transcriptional regulation by a repressor protein.

SOURCE Monod, J. 1965. "From Enzymatic Adaption to Allosteric Transitions." Nobel Prize lecture. [http://nobelprize.org/nobel\\_prizes/medicine/laureates/1965/monod-lecture.htm](http://nobelprize.org/nobel_prizes/medicine/laureates/1965/monod-lecture.htm).

To understand how the genes for lactose utilization are regulated, you need to know the main players, and these are shown in [Fig. 18.15](#). Let's start with the two coding sequences on the right side of the figure, in yellow and green:

- *lacZ* is the gene (coding sequence) for the enzyme  $\beta$ -galactosidase, which cleaves the lactose molecule into its glucose and galactose constituents. A functional, nonmutant form of the *lacZ* gene is denoted as *lacZ*<sup>+</sup>.
- *lacY* is the gene (coding sequence) for the protein lactose permease, which transports lactose from the external medium into the cell. A functional, nonmutant form of the *lacY* gene is denoted as *lacY*<sup>+</sup>.

These genes are called **structural genes** because they code for the sequence of amino acids making up the primary structure of each protein. Bacteria that contain mutations that eliminate function of the *lacZ* gene (denoted as *lacZ*<sup>−</sup> mutants) or those that eliminate function of the *lacY* gene (denoted as *lacY*<sup>−</sup> mutants), cannot utilize lactose as a source of energy. Without a functional product from *lacY*, lactose cannot enter the cell, and without a functional product from *lacZ*, lactose cannot be cleaved into its component sugars. A functional form of  $\beta$ -galactosidase (*lacZ*<sup>+</sup>) and of permease (*lacY*<sup>+</sup>) are both essential for the utilization of lactose and for cell growth.

Regulation of the *lacZ* and *lacY* structural genes is controlled by the product of another structural gene, called *lacI* (purple in [Fig. 18.15](#)), which encodes a repressor protein. Located between *lacI* and *lacZ* are a series of regulatory sequences for *lacZ* and *lacY* that include a promoter, *lacP* (light green), whose function is to recruit the RNA polymerase complex and initiate transcription, and an **operator**, *lacO* (orange), which is the binding site for the repressor. Another regulatory region is a binding site for a protein called CRP, which is discussed later.

The *lacZ* and *lacY* genes share a single set of regulatory elements and are transcribed together—a gene organization that is common in bacteria. Typically, a group of functionally related genes are located next to one another along the bacterial DNA and they share a promoter. Subsequently, when the coding sequences of the structural genes are transcribed from the promoter, they are transcribed together into a single molecule of mRNA. Such an mRNA is called a **polycistronic**

**mRNA** (“cistron” is an old term for “coding sequence”). In [Fig. 18.15](#), the polycistronic RNA includes the coding sequences for  $\beta$ -galactosidase and lactose permease. The region of DNA consisting of the promoter, the operator, and the coding sequence for the structural genes is called an **operon**.

Operons are found in bacteria and archaeons, whose cells can translate polycistronic mRNA molecules correctly because their ribosomes can initiate translation anywhere along an mRNA that contains a proper ribosome-binding site ([Chapter 4](#)). In a polycistronic mRNA, each of the coding sequences is preceded by a ribosome-binding site, so translation can be initiated at each coding sequence.

## The repressor protein binds with the operator and prevents transcription, but not in the presence of lactose.

The lactose operon is negatively regulated by the repressor protein encoded by the *lacI* gene. That is, the structural genes of the lactose operon are always expressed unless the operon is turned off by a regulatory molecule, in this case the repressor. [Fig. 18.16a](#) shows what the operon looks like in the absence of lactose. The *lacI* gene, which is encoding the repressor protein, is expressed constantly at a low level. The repressor protein binds with the operator (*lacO*), the RNA polymerase complex is not recruited, and transcription does not take place.

FIG. 18.16 Repression and induction of the lactose operon. (a) In the absence of lactose, transcription is repressed. (b) In the presence of lactose, transcription is induced.

The configuration of the lactose operon in the presence of lactose is shown in [Fig. 18.16b](#). When lactose is present in the cell, the repressor protein is unable to bind to the operator, RNA polymerase is recruited, and transcription occurs. In other words, lactose acts as an inducer of the lactose operon because it prevents binding of the repressor protein and results in derepression. The inducer is not actually lactose itself, but rather an isomer of lactose called allolactose, which differs in the way the sugars are linked. Lactose in the cell is always accompanied by a small amount of allolactose, and so induction of the lactose operon occurs in the presence of lactose.

The binding of the inducer to the repressor results in an allosteric change in repressor structure that inhibits the protein's ability to bind to the operator. The absence of repressor from the operator allows the RNA polymerase complex to be recruited to the promoter, and the polycistronic mRNA is produced. The resulting lactose permease

allows lactose to be transported into the cell on a large scale, and  $\beta$ -galactosidase cleaves the molecules to allow the constituents to be used as a source of energy and carbon. Therefore, the lactose operon is an example of negative regulation by a repressor, whose function is modulated by an inducer.

## The function of the lactose operon was revealed by genetic studies.

Although the interactions shown in [Fig. 18.16](#) have since been confirmed by direct biochemical studies, the inferences about how the repressor and operator work were originally drawn from studies of mutations ([Fig. 18.17](#)). As part of their investigation, Jacob and Monod identified bacterial mutants that always expressed  $\beta$ -galactosidase and permease, even in the absence of lactose. The phenotype of a cell carrying such a mutation is said to be **constitutive** for production of the proteins. Constitutive expression means that expression occurs continuously. The most common constitutive phenotype resulted from a mutation in the *lacI* gene (*lacI<sup>-</sup>* mutants) that produced a defective repressor protein ([Fig. 18.17a](#)).

FIG. 18.17 Lactose operon regulatory mutants. Jacob and Monod's results with repressor and operator mutants. (a) A cell with a mutant repressor protein produces the enzymes constitutively. (b) Addition of a nonmutant repressor restores normal regulation. (c) A cell with a mutant operator region produces the enzymes constitutively. (d) Addition of a nonmutant operator region fails to restore normal regulation, and the enzymes continue to be produced constitutively.

Jacob and Monod also conducted experiments in which *E. coli* contained not one but two lactose operons ([Fig. 18.17b](#)). In bacterial cells containing one mutant and one nonmutant copy of the *lacI* repressor gene in the absence of lactose, expression of the structural genes was no longer constitutive but instead showed normal regulation. This finding is consistent with the idea that the nonmutant form of the gene produces a diffusible protein, which implies that the normal repressor is able to bind to and repress transcription from both operons,

not just the one to which it is physically linked.

A much less common class of constitutive mutants identified the operator ([Fig. 18.17c](#)). Genetic studies of the mutations in these cells showed that they were not located in the *lacI* gene that encodes the repressor but, instead, a genetic element closer to the *lacZ* sequence, called the lactose operator (*lacO*). The constitutive mutations were designated *lacO<sup>c</sup>* (“c” for “constitutive”). When two different lactose operons, one normal and one with the *lacO<sup>c</sup>* mutation, were in the same cell in the absence of lactose, the operon carrying *lacO<sup>c</sup>* was transcribed constitutively, even in the presence of the normal repressor, because the repressor was unable to bind to the mutant operator site in *lacO<sup>c</sup>* ([Fig. 18.17d](#)). Jacob and Monod wrote that “to explain this effect, it seems necessary to invoke a new type of genetic entity, called an ‘operator,’ which would be: (a) adjacent to the group of [structural] genes and would control their [transcriptional] activity; and (b) would be sensitive to the repressor produced by a particular regulatory gene.”

## The lactose operon is also positively regulated by CRP–cAMP.

[Fig. 18.16](#) shows how the ability of the repressor to bind with either the operator (in the absence of lactose) or with the inducer (in the presence of lactose) provides a simple and elegant way for the bacterial cell to transcribe the genes needed for lactose utilization only in the presence of lactose. The elucidation of these interactions was as far as the research tools used by Jacob and Monod could take them. Since the original experiments, the lactose operon has been studied in much greater detail and additional levels of regulation have been discovered.

One of these additional levels involves the CRP binding site shown in light blue in [Fig. 18.15](#), which in [Fig. 18.18](#) is occupied by a protein called the CRP–cAMP complex. The CRP–cAMP complex is a positive regulator of the lactose operon, which you will recall is a protein that activates gene expression upon binding DNA. “CRP” stands for “cAMP receptor protein,” and the CRP–cAMP complex is a molecule of CRP bound to a molecule of cAMP. The role of CRP–cAMP is to provide another level of control of transcription that is more sensitive to the nutritional needs of the cell than the level of control provided by the presence or absence of lactose. *E. coli* can utilize many kinds of molecules as sources of energy. When more than one type of energy source is available in the environment, certain sources are used before others. For example, glucose is preferred to lactose, and lactose is preferred to glycerol. The CRP–cAMP complex helps regulate which compounds are utilized.

**FIG. 18.18** The CRP–cAMP complex, a positive regulator of the lactose operon. (a) In the absence of large amounts of glucose, cAMP levels are high and the CRP–cAMP complex binds to a site near the promoter, where it activates transcription. (b) In the presence of large amounts of glucose, cAMP levels are low and the CRP–cAMP complex does not bind, so transcription is not induced to high levels, even

in the presence of lactose.

The concentration of the small molecule cAMP in the cell is a signal about the nutritional state of the cell. When there are low levels of glucose, cAMP levels are high. cAMP binds to CRP, changing the shape of CRP so that it can bind at a site near the operator and stimulate binding of RNA polymerase to transcribe *lacZ* and *lacY* when lactose is present in the cell ([Fig. 18.18a](#)). In this way, cAMP is an allosteric activator of CRP binding. However, if lactose is not present in the cell, the lactose repressor binds to the lactose operator and prevents transcription, even in the presence of the cAMP–CRP complex.

When glucose is abundant, cAMP levels are low, and the cAMP–CRP complex does not bind the lactose operon. As a result, even in the presence of lactose, the lactose operon is not transcribed to high levels ([Fig. 18.18b](#)). In this way, *E. coli* preferentially utilizes glucose when both glucose and lactose are present, and it utilizes lactose only when glucose is depleted.

## Transcriptional regulation determines the outcome of infection by a bacterial virus.

Transcriptional regulation has also been well studied in viruses. Bacterial cells are susceptible to infection by a variety of viruses known as [bacteriophages](#) (“bacteriophage” literally means “bacteria-eater,” and is often shortened to just “phage”). Among bacteriophages

is a type that can undergo one of two fates when infecting a cell. The best-known example is bacteriophage  $\lambda$  (lambda), which infects cells of *E. coli*. The possible results of  $\lambda$  infection are illustrated in [Fig. 18.19](#).

Upon infection, the virus injects its linear DNA genome into the bacterial cell, and almost immediately the ends of the molecule join to form a circle. In normal cells growing in nutrient medium, the usual outcome of infection is the **lytic pathway**, shown on the left side of [Fig. 18.19](#). In the lytic pathway, the virus hijacks the cellular machinery to replicate the viral genome and produce viral proteins. After about an hour, the infected cell undergoes **lysis** and bursts open

to release a hundred or more progeny phage that are capable of infecting other bacterial cells.

The alternative to the lytic pathway is **lysogeny**, shown on the right side of [Fig. 18.19](#). In lysogeny, the bacteriophage DNA integrates into the bacterial DNA by undergoing recombination at a specific site in both molecules. Lysogeny often takes place in cells that are growing in poor conditions. The relative sizes of the DNA molecules in [Fig. 18.19](#) are not to scale. In reality, the length of the bacteriophage DNA is only about 1% of that of the bacterial DNA. When the bacteriophage DNA is integrated by lysogeny, the only bacteriophage gene transcribed and translated is one that represses the transcription of other phage genes, preventing entry into the lytic pathway. The bacteriophage DNA is replicated along with the bacterial DNA and transmitted to the bacterial progeny when the cell divides. Under stress, such as exposure to ultraviolet light, recombination is reversed, freeing the phage DNA and initiating the lytic pathway.

At the molecular level, the choice between the lytic and lysogenic pathways is determined by the positive and negative regulatory effects of a small number of bacteriophage proteins produced soon after infection. Which pathway results depends on the relative production of a protein known as *cro* and that of another protein known as *cI*. If the production of *cro* predominates, the lytic pathway results; if *cI* predominates, the lysogenic pathway takes place.

[Fig. 18.20a](#) shows the small region of the bacteriophage DNA in which the key interactions take place. Almost immediately after

infection and circularization of the bacteriophage DNA, transcription takes place from the promoters  $P_L$  and  $P_R$ . Transcription of genes controlled by the  $P_R$  promoter results in a transcript encoding the proteins *cro* and *cII*. The *cro* protein represses transcription of a gene controlled by another promoter  $P_M$ , whose transcript encodes the protein *cI*. In normal cells growing in nutrient medium, proteases present in the bacterial cell degrade *cII* and prevent its accumulation. With *cro* protein preventing *cI* expression and *cII* protein being unable to accumulate, transcription of bacteriophage genes in the lytic pathway takes place, including those genes needed for bacteriophage DNA replication, those encoding proteins in the bacteriophage head and tail, and, finally, those needed for lysis.

FIG. 18.20 Transcriptional regulation of *cI* and *cro* genes, which determines whether the viral pathway is lytic (a) or lysogenic (b).

Alternatively, in bacterial cells that are growing in poor conditions (Fig. 18.20b), reduced protease activity allows *cII* protein to

accumulate. When cII protein reaches a high enough level, it stimulates transcription from the promoter  $P_E$ . Transcription from  $P_E$  proceeds through  $P_M$  and continues farther to include the coding sequence for cI protein. The cI protein has three functions:

- It binds with the operator  $O_R$  and prevents further expression of *cro* and *cII*.
- It stimulates transcription of its own coding sequence from the promoter  $P_M$ , establishing a positive feedback loop that keeps the level of cI protein high.
- It binds with the operator  $O_L$  and prevents further transcription from  $P_L$ .

The result is that cI production shuts down transcription of all bacteriophage genes except its own gene, and this is the regulatory state that produces lysogeny. (The protein needed for integration of the bacteriophage DNA into the bacterial DNA is produced by transcription from the  $P_L$  promoter before it is shut down by cI.) When cells that have undergone lysogeny are exposed to ultraviolet light or certain other stresses, the cI protein is degraded. In this case, *cro* and *cII* are produced again, and the lytic pathway follows.

Regulation of the lytic and lysogenic pathways works to the advantage of bacteriophage  $\lambda$ , but the process is not like something an engineer might design. That is because biological systems are not engineered—they evolve. Regulatory mechanisms are built up over time by the selection of successive mutations. Each evolutionary step refines the regulation in such a way as to be better adapted to the

We summarize these two alternative outcomes of infection by a bacterial virus, and the earlier discussions of viral diversity, replication, host range, and effects on a cell, in [Fig. 18.21](#).

## Self-Assessment Questions

8. How can the binding of a molecule as small as a single amino acid change the ability of a large, multi-subunit protein molecule to bind a specific DNA sequence?
9. What would be the consequence of a mutation in the *lacI* repressor gene that produces repressor protein that is able to bind to the operator but is not able to bind allolactose?

10. What is the role of the CRP–cAMP complex in positive regulation of the lactose operon in *E. coli*?
11. How are the lytic and lysogenic pathways regulated?

## CORE CONCEPTS SUMMARY

### 18.1 CHROMATIN TO MESSENGER RNA IN EUKARYOTES:

Gene expression in eukaryotes can be regulated at the level of DNA packaging in chromosomes, transcription, and RNA processing.

Gene expression involves the turning on or turning off of a gene, whereas gene regulation determines where, when, how much, and which gene product is made. [page 377](#)

Regulation at the level of chromatin involves chemical modifications of DNA and histones that make a gene accessible or inaccessible to the transcriptional machinery. [page 378](#)

Dosage compensation is the process by which the expression of *X*-linked genes is equalized in *XX* individuals and *XY* individuals. [page 380](#)

*X*-inactivation, the mechanism of dosage compensation for sex chromosomes in mammals, involves the inactivation of one of the two *X* chromosomes in females. [page 380](#)

*X*-inactivation occurs by the transcription of a noncoding RNA known as *Xist*, which coats the entire *X* chromosome, leading to DNA and histone modifications and transcriptional repression. [page 381](#)

Transcriptional regulation controls whether or not transcription of a gene occurs. [page 381](#)

Transcription can be regulated by regulatory transcription factors that bind to specific DNA sequences known as enhancers that can

be near, in, or far from genes. [page 382](#)

Further levels of regulation after a gene is transcribed to mRNA include RNA processing, splicing, and editing. [page 382](#)

## **18.2 MESSENGER RNA TO PHENOTYPE IN EUKARYOTES:**

After an mRNA is exported to the cytoplasm, gene expression in eukaryotes can be regulated at the level of mRNA stability, translation, and posttranslational modification of proteins.

Small regulatory RNAs, especially microRNA (miRNA) and small interfering RNA (siRNA), affect gene expression through their effects on translation or mRNA stability. [page 384](#)

Translational regulation controls the rate, timing, and location of protein synthesis. [page 384](#)

Translational regulation is determined by many features of an mRNA molecule, including the 5' and 3' UTR, the cap, and the poly(A) tail. [page 385](#)

Posttranslational modification comes into play after a protein is synthesized, and includes chemical modification of side groups of amino acids, affecting the structure and activity of a protein. [page 385](#)

Gene regulation is influenced by both genetic and environmental factors. [page 386](#)

## **18.3 TRANSCRIPTIONAL REGULATION IN PROKARYOTES:**

Gene expression in prokaryotes can be regulated at the level of transcription in response to environmental conditions.

Transcriptional regulation can be positive, in which a gene is usually off and is turned on in response to the binding to DNA of a regulatory protein called an activator, or negative, in which a gene is usually on and is turned off in response to the binding to DNA of a regulatory protein called a repressor. [page 386](#)

Jacob and Monod demonstrated how production of the enzymes encoded in the lactose operon in *E. coli* occurs only in the presence of lactose in the culture medium. [page 388](#)

When lactose is added to culture of bacteria, the genes for enzymes that facilitate the uptake of lactose (permease, encoded by *lacY*) and cleavage of lactose ( $\beta$ -galactosidase, encoded by *lacZ*) are expressed. [page 388](#)

The lactose operon is negatively regulated by the repressor protein (encoded by *lacI*), which binds to a DNA sequence known as the operator when lactose is absent and prevents transcription of *lacY* and *lacZ*. [page 389](#)

When lactose is added to the medium, it induces an allosteric change in the repressor protein, preventing it from binding to the operator and allowing transcription of *lacY* and *lacZ*. In this way, lactose acts as an inducer of the lactose operon. [page 389](#)

An additional level of regulation of the lactose operon is provided by the CRP–cAMP complex, a positive activator of transcription that stimulates the operon when glucose is scarce. [page 390](#)

The lytic and lysogenic pathways of bacteriophage  $\lambda$  have also been well studied as a model of gene regulation. When bacteriophage  $\lambda$

infects *E. coli*, it can lyse the cell (the lytic pathway) or its DNA can become integrated into the bacterial genome (the lysogenic pathway). [page 391](#)

In infection of *E. coli* cells by bacteriophage  $\lambda$ , predominance of cro protein results in the lytic pathway, whereas predominance of the cI protein results in the lysogenic pathway. [page 392](#)

## CHAPTER 19 Genes and Development

Perennou Nuridsany/Science Source

---

### CORE CONCEPTS

**19.1 GENETIC BASIS OF DEVELOPMENT:** In the development of humans and other animals, stem cells become progressively more restricted in their possible pathways of cellular differentiation.

**19.2 HIERARCHICAL CONTROL:** The genetic control of development is a hierarchy in which genes are activated in groups that, in turn, regulate the next set of genes.

**19.3 MASTER REGULATORS:** Many master regulators that play key roles in development are evolutionarily conserved but can have dramatically different effects in different organisms.

**19.4 COMBINATORIAL CONTROL:** Combinatorial control is a developmental strategy in which cellular differentiation depends on the particular combination of transcription factors present in a cell.

**19.5 CELL SIGNALING IN DEVELOPMENT:** Ligand–receptor interactions activate signal transduction pathways that converge on transcription factors and genes that determine cell fate.

---

Altogether, the human body contains about 200 different types of cell, all of which derive from a single cell, the zygote. Some cells derived from the zygote become muscle cells, others nerve cells, and still others liver cells. All of these cells have almost exactly the same genome: they differ not in their content of genes, but instead in the groups of genes that are expressed or repressed. In other words, these cell types differ as a result of gene regulation, which was discussed in [Chapter 18](#).

Gene regulation is especially important in any multicellular organism because it underlies [development](#), the process in which a

fertilized egg undergoes multiple rounds of cell division to become an embryo with specialized tissues and organs. During development, cells undergo changes in gene expression as genes are turned on and off at specific times and places. Gene regulation causes cells to become progressively more specialized, a process known as **differentiation**.

In this chapter, we focus on the general principles by which genes control development. We will see that, as cells differentiate along one pathway, they progressively lose their ability to differentiate along other pathways. Yet gene expression can sometimes be reprogrammed to reopen pathways of differentiation that had previously been shut off, a process that has important medical applications in therapeutic replacement of diseased or damaged tissue. From a broader perspective, the study of evolutionary changes in developmental processes constitutes the field of evolutionary developmental biology, which is often called **evo-devo**. We will see that, although some of the key molecular mechanisms of development are used over and over again in different organisms, they have evolved to yield such differences in shape and form as to conceal the underlying similarity in mechanism.

# 19.1 GENETIC BASIS OF DEVELOPMENT

Genetic programs and computer programs have some features in common. Computer code is written as a linear string of letters, analogous to the sequence of nucleotides in genomic DNA. Once a computer program is initiated, it automatically runs and performs its coded task. Small mistakes in the code, like mutations, can have big consequences and even cause the program to crash.

The analogy between genetic programs and computer programs has an important limitation. Computer programs are consciously written, whereas genetic programs evolve. The genetically encoded developmental programs of all living organisms emerged over billions of years through mutation and natural selection. These developmental programs changed through time, persisting only if they produced organisms that could successfully survive and reproduce in the existing environment. Here, we explore the genetic program of development—that is, the genetic instructions that lead a single fertilized egg to become a complex multicellular organism.

## The fertilized egg is a totipotent cell.

In all sexually reproducing organisms, the fertilized egg is special because of its developmental potential. The fertilized egg is said to be **totipotent**, which means that it can give rise to a complete organism. In mammals, the egg also forms the membranes that surround and support the developing embryo ([Chapter 40](#)).

In humans, after fertilization, the fertilized egg, or **zygote**, undergoes successive mitotic cell divisions as it moves along a fallopian tube. One cell becomes two, two become four, four become eight, eight become sixteen, and so on, with all the cells contained within the egg's tough outer glycoprotein layer (**Fig. 19.1**). Within 4–5 days after fertilization, the zygote has turned into a ball of cells called the **morula** and has traveled from the site of fertilization in one of the fallopian tubes to the uterus.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 19.1 Early development of a human embryo. The zygote is a totipotent cell because its daughter cells can develop into any cell type and eventually into a complete organism.

These early cell divisions are different from the mitotic cell divisions that occur later in life because the cells do not grow between divisions; they merely replicate their chromosomes and divide again. The result is that the cytoplasm of the egg is partitioned into smaller

and smaller cells, with the new cells all bunched together inside the membrane that surrounds the developing embryo.

Cell division continues in the morula until there are a few thousand cells. The cells then begin to move relative to one another, pushing against and expanding the membrane that encloses them and rearranging themselves to form a hollow sphere called a **blastocyst** ([Fig. 19.1](#)). Attached to the inside of the wall in one region of the blastocyst is a group of cells known as the **inner cell mass**, from which the body of the embryo develops. The wall of the blastocyst forms several membranes that envelop and support the developing embryo. Once the blastocyst forms, it implants in the uterine wall.

Once implanted in the uterine wall, the multiplying cells of the inner cell mass migrate and reorganize to form a **gastrula**, in which the cells of the blastula become organized into three **germ layers** ([Fig. 19.1](#)). The germ layers are sheets of cells called the ectoderm, mesoderm, and endoderm. These layers of cells differentiate further into specialized cells. Those formed from the **ectoderm** include the outer layer of the skin and nerve cells in the brain; cells formed from the **mesoderm** include cells that make up the inner layer of the skin, muscle cells, and red blood cells; and cells formed from the **endoderm** include cells of the lining of the digestive tract and lung, as well as liver cells and pancreas cells ([Chapter 40](#)).

## Cellular differentiation increasingly restricts alternative fates.

At each successive stage in development in which the cells

differentiate, they lose the potential to develop into any kind of cell. The fertilized egg is a totipotent cell because it can differentiate into both the inner cell mass and supporting membranes, and eventually into an entire organism. The cells of the inner cell mass, called embryonic stem cells, are **pluripotent** because they can give rise to any of the three germ layers, and therefore to any cell of the body. However, pluripotent cells cannot give rise to an entire organism on their own, as a totipotent cell can. Cells further along in differentiation are **multipotent**; these cells can form a limited number of types of specialized cell. Cells of the germ layers are multipotent because they can give rise only to the cell types specified for each germ layer in [Figure 19.1](#). Totipotent, pluripotent, and multipotent cells are all **stem cells**, which are cells that are capable of differentiating into different cell types.

Why do differentiating cells increasingly lose their developmental potential? One hypothesis focuses on gene regulation. When cells become committed to a particular developmental pathway, genes that are no longer needed are turned off (that is, repressed) and are difficult to turn on again. Another hypothesis is genome reduction: as cells become differentiated, they delete DNA for genes they no longer need.

These hypotheses can be distinguished by an experiment in which differentiated cells are placed in an environment that reprograms them to mimic earlier states. If loss of developmental potential is due to gene regulation, then differentiated cells could be reprogrammed to become pluripotent or multipotent. If loss of developmental potential is due to genome reduction, then differentiated cells could not be reprogrammed

to become pluripotent or multipotent because the genes for alternate developmental routes are no longer present.

British developmental biologist John Gurdon carried out such experiments in the early 1960s ([Fig. 19.2](#)). Gurdon used a procedure called [nuclear transfer](#), in which a hollow glass needle is used to insert the nucleus of a cell into the cytoplasm of an egg whose own nucleus has been destroyed or removed. Previous nuclear transfer experiments had been carried out in the leopard frog, *Rana pipiens*. Whereas nuclei from pluripotent or multipotent cells could often be reprogrammed to develop into normal tadpoles, attempts with nuclei from fully differentiated cells failed. In other words, Gurdon's findings supported the first hypothesis: all of the same genes are present in intestinal cells as in early embryonic cells, but some of the genes are turned off, or repressed, during development.

#### HOW DO WE KNOW?

### FIG. 19.2

## How do stem cells lose their ability to differentiate into any cell type?

#### BACKGROUND

During differentiation, cells become progressively more specialized and restricted in their fates. Early studies left the mechanisms of differentiation unclear.

#### HYPOTHESIS

One hypothesis is that differentiation occurs when patterns of gene expression in the cell change as it develops and genes that are no longer needed are repressed. An alternative hypothesis is that differentiation

occurs as a result of genome reduction, in which genes that are not needed are deleted.

### EXPERIMENT

John Gurdon carried out experiments in the amphibian *Xenopus laevis* to test these hypotheses. He transferred nuclei from differentiated cells (in this case, intestinal cells) into unfertilized eggs whose nuclei had been inactivated with ultraviolet light. Despite the nucleus being degraded, the egg cytoplasm still contains the molecules that would have kept the nucleus in an undifferentiated state. If differentiation is due to changes in gene expression, then the molecules in the egg cytoplasm should be able to reprogram the differentiated nucleus into an earlier state, and the reprogrammed nucleus should be able to differentiate again into all the cells of a tadpole. If differentiation is accompanied by loss of genes, then differentiation is irreversible and development cannot proceed.

### RESULTS

The experiment was carried out 726 times. In 716 cases, development did not occur; in 10 cases, development proceeded normally.

### CONCLUSION

Although the experiment succeeded in only 10 of 726 attempts, it

demonstrated that the nucleus of a differentiated cell and the cytoplasm of the unfertilized egg were able to support complete development of a normal animal. This result allowed Gurdon to reject the hypothesis that differentiation occurs by the loss of genes. The first hypothesis—that cells become differentiated as a result of changes in gene expression—was supported. However, because of the small number of successes in reprogramming, additional experiments were needed to validate the conclusions.

#### FOLLOW-UP WORK

Gurdon's work was controversial. Some critics argued that the successful experiments resulted from a small number of undifferentiated cells present in intestinal epithelium. Others accepted the conclusion but expressed misgivings about possible applications to humans. Later experiments that succeeded in cloning mammals from fully differentiated cells confirmed Gurdon's original conclusion.

SOURCE Gurdon, J. B. 1962. "The Developmental Capacity of Nuclei Taken from Intestinal Epithelium Cells of Feeding Tadpoles." *Journal of Embryology & Experimental Morphology* 10:622–640.

**Fig. 19.3** summarizes the results of many nuclear transfer experiments carried out in mammals and amphibians. The percentage of reprogramming experiments that fail increases as cells differentiate. The best chance of success is to use pluripotent nuclei from cells in the blastocyst (or its amphibian equivalent, the blastula). However, even some experiments using nuclei from fully differentiated cells have been successful.

FIG. 19.3 Results of nuclear transfer of differentiated cells. *Data from: J. B. Gurdon and D. A. Melton, "Nuclear Reprogramming in Cells," 2008, Science 322:1811–1815.*

When nuclear transfer succeeds, the result is a **clone**—an individual that carries an exact copy of the nuclear genome of another individual. In this case, the new individual shares the same genome as that of the individual from which the donor nucleus was obtained. (The mitochondrial DNA is not from the nuclear donor, but from the donor of the egg cytoplasm.) The first mammalian clone was a lamb called Dolly (**Fig. 19.4a**), born in 1996. She was produced from the transfer of the nucleus of a cell in the mammary gland of a sheep to an egg cell with no nucleus, and was the only successful birth among 277 nuclear transfers. Successful cloning in sheep soon led to cloning in cattle, pigs, and goats.

Sources: a. JOHN CHADWICK/AP Images; b. PAT SULLIVAN/AP Images .

FIG. 19.4 Celebrity clones and their genetic mothers. (a) Dolly; (b) CopyCat.

The first household pet to be cloned was a kitten named CopyCat ([Fig. 19.4b](#)), born in 2001 and derived from the nucleus of a differentiated ovarian cell. CopyCat was the only success among 87

attempts. As shown in [Fig. 19.4b](#), the cat from which the donor nucleus was obtained was a calico, but CopyCat herself was not, even though the two cats were clones of each other. The reason for their different appearance has to do with X-inactivation, discussed in [Chapter 18](#). Recall that the mottled orange and black calico pattern results from random inactivation of one of the two *X* chromosomes during development. The lack of a calico pattern in CopyCat implies that the *X* chromosomes in the transferred nucleus did not “reset” as they do in normal embryos. Instead, the inactive *X* in the donor nucleus remained inactive in all the cells in the clone. Thus, although CopyCat and her mother share the same nuclear genome, the genes were not expressed in the same way because of irreversible epigenetic regulation in the donor nucleus.

---

### CASE 3 YOUR PERSONAL GENOME: YOU, FROM A TO

T

## Can cells with your personal genome be reprogrammed for new therapies?

Stem cells play a prominent role in [regenerative medicine](#), which aims to use the natural processes of cell growth and development to replace diseased or damaged tissues. Stem cells are already used in bone marrow transplantation and may someday be used to treat Parkinson’s disease, Alzheimer’s disease, heart failure, certain types of diabetes, severe burns and wounds, and spinal cord injury.

At first, it seemed as though the use of embryonic stem cells gave the greatest promise for regenerative medicine because of their pluripotency. This approach proved ethically controversial because obtaining embryonic stem cells requires the destruction of human blastocysts—that is, early-stage embryos. A major breakthrough occurred in 2006 when Japanese scientists demonstrated that adult cells can be reprogrammed by activation of just a handful of genes, most of them encoding transcription factors or chromatin proteins. The reprogrammed cells were pluripotent and were therefore called [induced pluripotent stem cells \(iPS cells\)](#).

The success rate was only about one iPS cell per thousand, and the genetic engineering technique required the use of viruses that can sometimes cause cancer. Nevertheless, the result was regarded as spectacular. Other researchers soon found other genes that could be used to reprogram adult cells into pluripotent or multipotent stem cells, and still other investigators developed virus-free methods for delivering the genes. In recent years, researchers have even discovered small organic molecules that can reprogram adult cells.

This kind of reprogramming opens the door to personalized stem cell therapies. The goal is to create stem cells derived from the adult cells of the individual patient. Because these cells contain the patient's own genome, problems with tissue rejection are minimized or eliminated ([Chapter 41](#)). There remains much to learn before therapeutic use of induced stem cells becomes routine. Researchers will face challenges such as increasing the efficiency of reprogramming, verifying that reprogramming is complete, making

sure that the reprogrammed cells are not prone to cancer, and demonstrating that the reprogrammed cells differentiate as they should. Nevertheless, researchers hope that someday soon, your own cells containing your personal genome could be reprogrammed to restore cells or organs damaged by disease or accident.

#### Self-Assessment Questions

1. The terms totipotent, pluripotent, and multipotent derive from Latin roots: *toti* (“all”), *pluri* (“more”), *multi* (“many”), and *potent* (“power”). Do these terms accurately convey the developmental potential of each type of cell?
2. From what you know about embryonic development, do you think that a cell from the inner cell mass or one from the ectoderm has more developmental potential? Why?
3. Explain how an individual’s own cells might be used in stem cell therapy.
4. X-inactivation can result in two clones of a cell that differ in the genes they express. Can you think of other reasons why two genetically identical individuals might look different from each other?

## 19.2 HIERARCHICAL CONTROL

During development of a complex multicellular organism, many genes are activated and repressed at different times, thus restricting cell fates. One of the key principles of development is that genes expressed early in an organism's development control the activation of other groups of genes that act later in development. Gene regulation during development is therefore **hierarchical**: genes expressed at each stage in the process control the expression of genes that act later.

### *Drosophila* development proceeds through egg, larval, and adult stages.

The fruit fly *Drosophila melanogaster* has played a prominent role in our understanding of the genetic control of early development, particularly the hierarchical control of development. Researchers have isolated and analyzed a large number of mutant genes that lead to a variety of defects at different stages in development. These studies have revealed many of the key genes and processes in development, which are the focus of the following sections.

The major events in *Drosophila* development are illustrated in **Fig. 19.5**. DNA replication and nuclear division begin soon after the egg and sperm nuclei fuse (**Fig. 19.5a**). Unlike in mammalian development, the early nuclear divisions in the *Drosophila* embryo occur without cell division; therefore, the embryo consists of a single cell with many nuclei in the center (**Fig. 19.5b**). When there are roughly 5000 nuclei, they migrate to the edge of the cell (**Fig. 19.5c**), where each nucleus

becomes enclosed in its own cell membrane, and together they form the **cellular blastoderm** (Fig. 19.5d).

FIG. 19.5 Life cycle of the fruit fly *Drosophila melanogaster*. The life cycle begins with (a) a fertilized egg, followed by (b–e) a developing embryo, (f–h) larval stages, (i) pupa, and (j) adult.

Then begins the process of **gastrulation**, in which the cells of the blastoderm migrate inward, creating layers of cells within the embryo. As in humans and most other animals ([section 19.1](#) and [Chapter 40](#)), gastrulation forms the three germ layers (ectoderm, mesoderm, and endoderm) that differentiate into different types of cell. A *Drosophila* embryo during gastrulation is shown in [Fig. 19.5e](#). At this stage, the embryo already shows an organization into discrete parts or segments, the formation of which is known as **segmentation**. There are three cephalic segments, C1–C3 (the term “cephalic” refers to the head); three thoracic segments, T1–T3 (the thorax is the middle region of an insect); and eight abdominal segments (A1–A8). Each of these

segments has a different fate in development.

About one day after fertilization, the embryo hatches from the egg as a larva ([Fig. 19.5f](#)). Over the next eight days, the larva grows and replaces its rigid outer shell, or cuticle, twice ([Figs. 19.5g](#) and [19.5h](#)). After a week of further growth, the cuticle forms a casing—called the pupa ([Fig. 19.5i](#))—in which the larva undergoes the dramatic developmental changes, known as metamorphosis, that give rise to the adult fruit fly.

## The egg is a highly polarized cell.

The ways in which genes control development in *Drosophila* was inferred from systematic studies of mutants by Christiane Nusslein-Volhard and Eric F. Wieschaus—work for which they were awarded the 1995 Nobel Prize in Physiology or Medicine. One of their findings was that development starts even before a zygote is formed, in the maturation of the [oocyte](#), which is the unfertilized egg cell produced by the mother. The oocyte, which matures under control of the mother's genes, is also important for normal embryonic development. This finding applies not only to insects like *Drosophila*, but also to many multicellular animals.

Among the striking mutants that Nusslein-Volhard and Wieschaus generated and investigated were ones that significantly affected early development ([Fig. 19.6](#)). These defects in very early development can be easily seen by the time the mutants reach the larval stage. In one class of mutants, called *bicoid*, larvae are missing segments at the anterior, or head, end. In another class of mutants, called *nanos*, larvae

are missing segments at the posterior, or tail, end. The mutant larvae are grossly abnormal and do not survive. Nusslein-Volhard and Wieschaus were able to identify each segment that was missing based on each segment's distinctive pattern of hairlike projections. In [Fig. 19.6](#), the patterns are shown as dark shapes on each segment.

FIG. 19.6 Normal and mutant *Drosophila* larvae. (a) Nonmutant larvae have anterior, middle, and posterior segments (b) *Bicoid* mutant larvae lack anterior segments. (c) *Nanos* mutant larvae lack posterior structures.

A distinguishing feature of *bicoid* and *nanos* mutants is that the abnormalities in the embryo depend on the genotype of the mother, not the genotype of the embryo. The reason the genotype of the mother can affect the phenotype of the developing embryo is that successful development requires the mother to produce a functioning oocyte before fertilization occurs. In *Drosophila* and many other organisms,

the composition of the egg includes macromolecules (such as RNA and protein) synthesized by cells in the mother and transported into the egg. If the mother carries mutations in her genes that inhibit proper development of the oocyte, the offspring can be abnormal. Genes such as *bicoid* and *nanos* that are expressed by the mother but affect the phenotype of the offspring (in this case, the developing embryo and larva) are called **maternal-effect genes**.

A normal *Drosophila* oocyte is highly polarized, meaning that one end is distinctly different from the other. For example, gradients of macromolecules define the anterior–posterior (head-to-tail) axis of the embryo as well as the dorsal–ventral (back-to-belly) axis. The best known of these gradients are those of messenger RNAs (mRNAs) that are transcribed from the maternal-effect genes *bicoid* and *nanos*. **Fig. 19.7a** shows the gradient of *bicoid* mRNA across the oocyte. The bulk of *bicoid* mRNA comes from the mother, and is localized in the anterior of the egg by proteins that attach the mRNA to the cytoskeleton.

FIG. 19.7 Gradients of *bicoid* and *nanos* mRNA and protein in the developing embryo. (a) The mRNA and protein for *bicoid* are localized in the anterior end of the egg. (b) The mRNA and protein for *nanos* are localized in the posterior end of the egg.

The mRNA corresponding to the maternal-effect gene *nanos* is also present in a gradient, but most of it is at the posterior end ([Fig. 19.7b](#)). Like *bicoid*, mRNA for *nanos* is synthesized by the mother's cells, and then imported into the oocyte during oogenesis. After fertilization, the zygote produces Bicoid and Nanos proteins from the localized mRNAs, and they have concentration gradients resembling those of the mRNAs in the oocyte ([Fig. 19.7](#)).

The anterior–posterior axis that is set up by the gradients of Bicoid and Nanos proteins is reinforced by gradients of two transcription factors called Caudal and Hunchback ([Fig. 19.8](#)). Like the mRNAs for Bicoid and Nanos, the mRNAs for Caudal and Hunchback are transcribed from the mother's genome and transported into the egg. As shown in [Fig. 19.8a](#), the mRNAs for *caudal* and *hunchback* are spread uniformly in the cytoplasm of the fertilized egg. However, the mRNAs are not translated uniformly in the unfertilized egg. Bicoid protein represses translation of *caudal*, and Nanos protein represses translation of *hunchback* ([Fig. 19.8b](#)). Caudal protein is therefore concentrated at the posterior end and Hunchback protein is concentrated at the anterior end. The expression of Caudal and Hunchback illustrates gene regulation at the level of translation, as discussed in [Chapter 18](#). Bicoid protein is also a transcription factor that promotes transcription of the *hunchback* gene from zygotic nuclei, which reinforces the localization

of Hunchback protein at the anterior end.

The Hunchback and Caudal gradients set the stage for the subsequent steps in development. The Hunchback transcription factor targets genes of the embryo needed for the development of anterior structures like eyes and antennae, and Caudal targets genes of the embryo needed for the development of posterior structures like genitalia. In this way, maternal genes expressed early in development

influence the expression of genes of the embryo that are important in later development. Because the products of the *bicoid* and *nanos* mRNA are the ones initially responsible for organizing the anterior and posterior ends of the embryo, respectively, mothers that are mutant for *bicoid* have larvae that lack anterior structures, and mothers that are mutant for *nanos* have larvae that lack posterior structures.

## Development proceeds by progressive regionalization and specification.

Nusslein-Volhard and Wieschaus also discovered mutants of the embryo's developmental genes. They discovered three classes of such mutants, and their analysis showed that genes in the embryo controlling its development are turned on in groups, and that each successive group acts to spatially restrict and further refine the pattern of differentiation generated by previous groups. This, too, is a general principle of development in many multicellular organisms.

The anterior–posterior gradient set up by the maternal-effect genes is first narrowed by genes called gap genes ([Fig. 19.9](#)), each of which is expressed in a broad region of the embryo. The name “gap gene” derives from the phenotype of mutant embryos, which are missing groups of adjoining segments, leaving a gap in the pattern of segments. [Fig. 19.9](#) shows the expression pattern of the gap gene *Krüppel*, which is expressed in the middle region of the embryo. Mutants of *Krüppel* lack some thoracic and abdominal segments when they reach the larval stage. *Krüppel* is expressed in the pattern shown in [Fig. 19.9](#) because it is under the control of the transcription factor Hunchback, which in this embryo is stained in green. High concentrations of Hunchback repress

*Krüppel* transcription entirely, and low concentrations fail to induce *Krüppel* transcription. Because Hunchback is present in an anterior–posterior gradient with high concentration at the anterior end and low concentration at the posterior end (see [Fig. 19.8](#)), the pattern of Hunchback expression means that *Krüppel* is transcribed only in the middle region of the embryo where Hunchback is present but not too abundant.

The gap genes encode transcription factors that control genes in the next level of the regulatory hierarchy, which consists of pair-rule genes

([Fig. 19.10](#)). Pair-rule genes receive their name because larvae with these mutations lack alternate body segments. The pair-rule gene illustrated in [Fig. 19.10](#) is *hairy*, whose mutants lack the odd-numbered thoracic segments and the even-numbered abdominal segments. The pair-rule genes help to establish the uniqueness of each of seven broad stripes across the anterior–posterior axis.

The pair-rule genes encode a set of transcription factors that help to regulate the next level in the segmentation hierarchy, which consists of segment-polarity genes ([Fig. 19.11](#)). The segment-polarity genes refine

the 7-striped pattern still further into a 14-striped pattern. Each of the 14 stripes has distinct anterior and posterior ends that are determined by the segment-polarity genes. Embryos with mutations in segment-polarity genes lose this anterior–posterior differentiation, with the result that the anterior and the posterior halves of each segment are mirror images. The example in [Fig. 19.11](#) is *engrailed*, which eliminates the posterior pattern element in each stripe and replaces it with a mirror image of the anterior pattern element.

# Homeotic genes determine where different body parts develop in the organism.

Together, the segment-polarity genes and other genes expressed earlier in the hierarchy control the pattern of expression of another set of genes called **homeotic (*Hox*) genes**. Originally discovered in *Drosophila*, homeotic genes encode some of the most important transcription factors in animal development. A homeotic gene is a gene that specifies the identity of a body part or segment during embryonic development. For example, homeotic genes instruct the three thoracic segments (T1, T2, and T3) each to develop a set of legs, and the second thoracic segment (T2) also to develop wings.

Two classic examples of the consequences of mutations in homeotic genes in *Drosophila* are shown in **Fig. 19.12**. **Fig. 19.12a** shows what happens when the homeotic gene *Antennapedia*, which specifies the development of the leg, is inappropriately expressed in anterior segments. The mutation causes legs to grow where antennae usually would. Similarly, a mutation in the homeotic gene *Bithorax* results in the transformation of thoracic segment 3 (T3) into thoracic segment 2 (T2), so that the fruit fly has two T2 segments in a row. As shown in the **Fig. 19.12b**, the result is a fruit fly with two complete sets of wings.

FIG. 19.12 Homeotic genes and segment identity. (a) Normal antennae are transformed into legs in an *Antennapedia* mutant. (b) Normal structures in the third thoracic segment are transformed into wings in a *Bithorax* mutant.

In *Drosophila*, the adult body parts such as legs, antennae, and wings are formed from specific tissues located throughout the larval body ([Fig. 19.13](#)). The development of these tissues and their metamorphosis into the adult body parts are regulated by the homeotic genes. First expressed at about the same time as the segment-polarity genes (see [Fig. 19.11](#)), the homeotic genes continue to be expressed even after the genes that regulate early development have shut down. Their continuing activity is due to the presence of chromatin remodeling proteins that keep the chromatin physically accessible to the transcription complex ([Chapter 18](#)).

Homeotic genes encode transcription factors. The domain of the homeotic transcription factors that binds DNA to promote or repress transcription is a sequence of 60 amino acids called a **homeodomain**, whose sequences are very similar from one homeotic protein to the next across different species.

The *Drosophila* genome contains eight *Hox* genes comprising two distinct clusters: the *Antennapedia* complex and the *Bithorax* complex (**Fig. 19.14**). The genes are arranged along the chromosome in the same order as their products function in anterior–posterior segments along the embryo. In addition, the timing of their expression corresponds to their order along the chromosome and location of expression, with genes that are expressed closer to the anterior end turned on earlier than genes that are expressed closer to the posterior

end. The correlation among linear order along the chromosome, anterior–posterior position in the embryo, and timing of expression is observed in *Hox* clusters in almost all organisms studied.

Because the amino acid sequences of the homeodomains of *Hox* gene products are very similar from one organism to the next, *Hox* gene clusters have been identified in a wide variety of animals with bilateral symmetry (organisms in which both sides of the midline are mirror images), from insects to mammals. Comparison of the number and types of *Hox* genes in different species supports the hypothesis that the ancestral *Hox* gene cluster had an organization very similar to what we now see in most organisms with *Hox* gene clusters. In its evolutionary history, the vertebrate genome was duplicated in its entirety twice; thus, vertebrates have four copies of the *Hox* gene

cluster ([Fig. 19.15](#)).

FIG. 19.15 Organization and content of *Hox* gene clusters in the mouse and the regions of the embryo in which they are expressed.

Unlike the *Hox* genes in *Drosophila*, mammalian *Hox* genes do not specify limbs but are important in the embryonic development of structures that become parts of the hindbrain, spinal cord, and vertebral column ([Fig. 19.15](#)). As in *Drosophila*, the genes in each cluster are expressed according to their linear order along the chromosome, which coincides with the head-to-tail order of regions that the genes affect in the embryo. Each gene helps to specify the identity of the region in which it is expressed. Many of the genes in the mammalian *Hox* clusters have redundant or overlapping functions so that learning exactly what each gene does continues to be a research challenge. The evolutionary and developmental study of *Hox* gene conservation and expression is a good example of recent evo-devo research.

#### Self-Assessment Questions

5. Would development happen normally if the mother has normal

*bicoid* function, but the embryo does not? Why or why not?

6. Draw a diagram to illustrate how a concentration gradient of a transcription factor along the anterior–posterior axis of a *Drosophila* embryo can create a region in the middle in which transcription of a target gene takes place without being transcribed in either the anterior or posterior region.
7. Would the pattern of segment-polarity gene expression be normal if one or more gap genes were not expressed properly? Why or why not?
8. Expression of a homeotic gene in the wrong tissue in *Drosophila* results in the development of an inappropriate body part from that tissue. Why does this happen?

## 19.3 MASTER REGULATORS

As we have seen, *Hox* genes and the proteins they encode are very similar in a wide range of organisms. As a result, they can be identified by their similarity in DNA or amino acid sequence. DNA or proteins that are similar in sequence among distantly related organisms are said to be **evolutionarily conserved**. Their similarity in sequence suggests that they were present in the most recent common ancestor and have changed very little over time because they carry out a vital function. Many transcription factors that are important in development are evolutionarily conserved. An impressive example is found in the development of animal eyes.

### Animals have evolved a wide variety of eyes.

Animal eyes show an amazing diversity in their development and anatomy (**Fig. 19.16**). Among the simplest eyes are those of the planarian flatworm (**Fig. 19.16a**), which are only pit-shaped cells containing light-sensitive photoreceptors. The planarian eye has no lens to focus the light, but the animal can perceive differences in light intensity. The incorporation of a spherical lens, as in some jellyfish (**Fig. 19.16b**), improves the image.

FIG. 19.16 Diversity of animal eyes.

Among the most complex eyes are the camera-type eyes of the squid ([Fig. 19.16c](#)) and human ([Fig. 19.16d](#)), which have a single lens to focus light onto a light-sensitive tissue, the retina ([Chapter 35](#)). Though the single-lens eyes of squids and vertebrates are similar in external appearance, they are vastly different in their development, anatomy, and physiology.

Some organisms, such as the house fly ([Fig. 19.16e](#)) and other insects, have compound eyes, that is, eyes consisting of hundreds of small lenses arranged on a convex surface and pointing in slightly different directions. This arrangement of lenses allows a wide viewing angle and detection of rapid movement.

In the history of life, eyes are very ancient. By the time of the extraordinary diversification of animals 542 million years ago (known as the Cambrian explosion), organisms such as trilobites ([Fig. 19.16f](#)) already had well-formed compound eyes. These differed greatly from the eyes in modern insects, however. For example, trilobite eyes had hard mineral lenses composed of calcium carbonate (the world's first safety glasses, so to speak). Altogether, about 96% of living animal species have true eyes that produce an image, as opposed to simply being able to detect differences in light intensity. Despite this common feature, the extensive diversity among the eyes of different organisms encouraged evolutionary biologists in the belief that the ability to perceive light may have evolved independently about 40 to 60 times.

## *Pax6* is a master regulator of eye development.

The wide diversity of structure and function of animal eyes suggests that eyes may have evolved independently in different organisms. However, more recent evidence suggests an alternative hypothesis—that they evolved once, very early in evolution, and subsequently diverged over time. One piece of evidence that supports the hypothesis of a single origin for light perception is the observation that the light-sensitive molecule in all light-detecting cells is the same, a derivative

of vitamin A in association with a protein called opsin ([Chapter 35](#)). The presence of the same light-sensitive molecule in diverse eyes argues that it may have been present in the common ancestor of all animals with eyes and has been retained over time.

Another argument against multiple independent origins of eyes came from studies of eye development. Researchers identified *eyeless*, a gene in the fruit fly *Drosophila*. As its name implies, the phenotype of *eyeless* mutants is abnormal eye development ([Fig. 19.17a](#)). When the protein product of the *eyeless* gene was identified, it was found to be a transcription factor called Pax6. Mutant forms of a *Pax6* gene were already known to cause small eyes in the mouse ([Fig. 19.17b](#)) and aniridia (absence of the iris) in humans.

eye phenotypes in *Drosophila*; (b) normal and mutant eye phenotypes in a mouse.

The mutations in the *Pax6* gene that cause the development defects in the eye in fruit flies, mice, and humans are classified as **loss-of-function mutations**. A loss-of-function mutation is a mutation that inactivates the normal function of a gene. For example, the mutation that causes the green color in Mendel's peas is a loss-of-function mutant of an enzyme that normally breaks down the green pigment chlorophyll, so the peas remain green and obscure the yellow pigments that are also present ([Chapter 15](#)). In the case of eye development, loss-of-function mutations in *Pax6* make a defective version of the Pax6 transcription factor that is not able to carry out its function.

The similarity in phenotypes of *Pax6* mutants, along with the strong conservation of Pax6 in *Drosophila* and mouse, led Swiss developmental biologist Walter Gehring to hypothesize that Pax6 might be a master regulator of eye development. In other words, he hypothesized that Pax6 binds to regulatory regions of a set of genes that turns on a developmental program that induces eye development. In theory, this means that Pax6 can induce the development of an eye in any tissue in which it is expressed.

To test this hypothesis, Gehring and collaborators genetically engineered fruit flies that would produce the normal Pax6 transcription factor in the antenna, where it is not normally expressed ([Fig. 19.18a](#)). Any mutation in which a gene is expressed in the wrong place or at the wrong time is known as a **gain-of-function mutation**. (We saw an example of gain-of-function mutations when the *Hox* genes were

expressed in the wrong segments of the fruit fly, producing legs where antennae normally develop and thus resulting in four-winged fruit flies.) For genes that control a developmental pathway, loss-of-function mutations and gain-of-function mutations often have opposite effects on phenotype.

FIG. 19.18 *Pax6*, a master regulator controlling eye development. (a) Normal fly antenna; (b) eye tissue induced by expression of fruit fly *Pax6* in the antenna; (c) eye tissue induced by expression of mouse *Pax6* in the antenna.

Because loss-of-function mutations in *Pax6* result in an eyeless phenotype, a gain-of-function mutation should result in eyes developing in whatever tissue *Pax6* is expressed. In the gain-of-function mutation, the antenna developed into a miniature compound eye, and electrical recordings demonstrated that some of these antennal eyes were functional ([Fig. 19.18b](#)). The researchers also created other gain-of-function mutations that led to eyes on the legs, wings, and other tissues, which the *New York Times* publicized in an article headlined “With New Fly, Science Outdoes Hollywood.”

Gehring and his group then went one step further. They took the

*Pax6* gene from mice and expressed it in fruit flies to see whether the mouse *Pax6* gene is similar enough to the fruit fly version of the gene that it could induce eye development in the fruit fly. Specifically, they created transgenic fruit flies that expressed the *Pax6* gene from mice in the fruit fly antenna. The mouse gene induced a miniature eye in the fly ([Fig. 19.18c](#)). However, the *Pax6* gene from mice induced the development of a compound eye of *Drosophila*, not the single-lens eye of mouse.

The ability of mouse *Pax6* to make an eye in fruit flies suggests that mouse and fruit fly *Pax6* are not only similar in DNA and amino acid sequence, but also similar in function, and indeed act as a master switch that can turn on a developmental program that leads to the formation of an eye. However, these observations led to another question: why did the mouse *Pax6* gene produce fruit fly eyes instead of mouse eyes?

The answer is that the fruit fly genome does not include the genes needed to make mouse eyes. Mouse *Pax6* protein induces fly eyes because it affects genes in the fly genome that function later in the process of eye development. The later-acting genes are called [downstream genes](#). Transcription factors like *Pax6* interact with their target genes by binding with short DNA sequences that are adjacent to the gene, usually at the 5' end, called [cis-regulatory elements](#). These regulatory elements help determine whether the adjacent DNA is transcribed. When bound to cis-regulatory elements, some transcription factors act as repressors that prevent transcription of the target gene, and others serve as activators by recruiting the transcriptional

machinery to the target gene ([Chapter 18](#)). A transcription factor can even repress some of its target genes and activate others.

In the fruit fly, Pax6 binds to cis-regulatory elements in many genes, turning some genes on and others off. The products of these downstream genes, in turn, affect the expression of further downstream genes. The total number of genes that are downstream of Pax6 and that are needed for eye development is estimated at about 2000. Most are not direct targets of Pax6, but they are activated indirectly through other transcription factors downstream of Pax6. When mouse Pax6 is expressed in fruit flies, it is similar enough in sequence to activate the genes involved in fruit fly eye development, so it makes sense that mouse Pax6 leads to the development of a fruit fly eye, not a mouse eye.

One scenario of how Pax6 became a master regulator for eye development in a wide range of organisms, yet produces a diversity of eyes in these organisms, is that Pax6 evolved early in the history of life as a transcription factor that was able to bind to and regulate genes involved in early eye development. Over time, different genes in different organisms acquired new Pax6-binding cis-regulatory elements by mutation, and if these were beneficial they persisted. Therefore, the downstream genes that are targets of Pax6 are different in different organisms, but they share two features: they are able to bind to and are regulated by Pax6, and they are involved in eye development. So, the early steps in eye development are conserved, but the later ones are not.

The *Pax6* gene and the *Hox* genes reveal an important principle in evo-devo, which is that master regulatory genes that control development are often evolutionarily conserved, whereas the downstream genes that they regulate may not be. Downstream genes can evolve new functions, or genes not originally controlled by the master regulator may evolve to come under its influence, or genes formerly controlled by the master regulator may evolve to be unresponsive. In this way, a conserved master regulatory mechanism may result in distinct developmental outcomes in different organisms. In the case of *Pax6*, for example, the master regulatory mechanism for eye development evolved early and is shared among a wide range of animals, even though the eyes that are produced are quite diverse.

#### Self-Assessment Questions

9. Why do master regulatory genes tend to be more strongly conserved in evolution than the downstream genes they regulate?
10. For genes that control pathways of development, loss-of-function mutations are usually recessive, whereas gain-of-function mutations are usually dominant. Why is this the case?

## 19.4 COMBINATORIAL CONTROL

Most cis-regulatory elements are composed of one or more binding sites for transcription factors, some of which are activators of transcription and others repressors of transcription. Therefore, the rate of transcription of any gene in any type of cell is determined by the combination of transcription factors that are present in the cell and by the relative balance of transcription factors that are activators versus those that are repressors. Regulation of gene transcription according to the mix of transcription factors in the cell is known as **combinatorial control**. Combinatorial control of transcription is another general principle often seen in all multicellular organisms at many stages of development. Here, we discuss flower development as an example of this general principle.

### Floral differentiation is a model for plant development.

The plant *Arabidopsis thaliana*, a weed commonly called mouse-ear cress, is a model organism for developmental studies and presents a clear case of combinatorial control. As in all plants, *Arabidopsis* has regions of undifferentiated cells, called meristems, where growth of shoots, roots, and flowers can take place ([Chapter 29](#)). Meristem cells are similar to stem cells in animals because they consist of multipotent cells that can differentiate into different structures in the flower. In floral meristems of *Arabidopsis*, the flowers develop from a pattern of four concentric circles of cells, or whorls, each of which differentiates

into a distinct type of floral structure.

From the outermost whorl (whorl 1) of cells to the innermost whorl (whorl 4), the floral organs are formed as shown in [Fig. 19.19](#):

- Cells in whorl 1 form the green sepals, which are modified leaves forming a protective sheath around the petals in the flower bud that unfold like petals when the flower opens.
- Cells in whorl 2 form the petals.
- Cells in whorl 3 form the stamens, which are the male sexual structures in which pollen is produced. (The small granules on the stamens in [Fig. 19.19](#) are pollen grains.)
- Cells in whorl 4 form the carpels, which are the female reproductive structures that receive pollen and contain the ovaries.

# The identity of the floral organs is determined by combinatorial control.

The genetic control of flower development in *Arabidopsis* was discovered by the analysis of mutant plants, an investigation similar in principle to the way that genetic control of development in fruit flies was determined. The plant mutants fell into three classes showing characteristic floral abnormalities ([Fig. 19.20](#)). A nonmutant (wild-type) flower is shown in [Fig. 19.20a](#). Mutations in the gene *apetala-2* inactivate the gene's function and affect whorls 1 and 2 ([Fig. 19.20b](#)); those in *apetala-3* or *pistillata* affect whorls 2 and 3 ([Fig. 19.20c](#)); and those in *agamous* affect whorls 3 and 4 ([Fig. 19.20d](#)). (Different standards are used for naming genes and proteins in different organisms. In *Arabidopsis*, wild-type alleles are written in capital letters with italics, and wild-type proteins in capital letters without italics. Mutant alleles and proteins follow the same rules but are written in lower-case letters.)

FIG. 19.20 Phenotypes of the normal flower and floral mutants of *Arabidopsis*.

The observation that the mutant phenotypes affect development of pairs of adjacent whorls already hints at combinatorial control, which researchers incorporated into a model of floral development called the **ABC model**. The model invokes three activities arbitrarily called A, B, and C. These activities represent the function of one or more different protein products of different genes that are hypothesized to be present in cells of each whorl as shown in [Fig. 19.21](#). In the course of floral differentiation, the cells of each whorl become different from those in the other whorls, and different combinations of genes are activated or repressed in each whorl. Activity A is present in whorls 1 and 2, activity B in whorls 2 and 3, and activity C in whorls 3 and 4. According to the ABC model, activity A alone results in the formation of sepals, A and B together result in petals, B and C together result in stamens, and C alone results in carpels. Like any good hypothesis ([Chapter 1](#)), this one makes specific predictions. Mutants lacking activity A will have defects in whorls 1 and 2; mutants lacking activity B will have defects in whorls 2 and 3; and mutants lacking activity C will have defects in whorls 3 and 4.

FIG. 19.21 The ABC model for flower development in *Arabidopsis*.

Matching these predictions with the mutants in [Fig. 19.20](#) yields the following correspondence:

- The A activity is encoded by the gene *APETALA-2*.
- The B activity is encoded jointly by the genes *APETALA-3* and *PISTILLATA*.
- The C activity is encoded by the gene *AGAMOUS*.

Comparing the mutant phenotypes in [Fig. 19.20](#) with the differentiation of the whorls in [Fig. 19.21](#), it is clear that the normal product of *APETALA-2* (A activity) is needed for proper development of whorls 1 and 2; the normal products of *APETALA-3* and *PISTILLATA* (together constituting B activity) are required for proper development of whorls 2 and 3; and the normal product of *AGAMOUS* (C activity) is needed for proper development of whorls 3 and 4. These inferences suggest that *APETALA-2* is normally expressed in whorls 1

and 2, *APETALA-3* and *PISTILLATA* in whorls 2 and 3, and *AGAMOUS* in whorls 3 and 4.

To account for all of the mutant phenotypes in [Fig. 19.20](#), you need only to postulate that when A is absent, C is expressed in whorls 1 and 2 in addition to its normal expression in whorls 3 and 4; and when C is absent, A expression expands into whorls 3 and 4 in addition to its normal expression in whorls 1 and 2. The domains of expression expand in this way because, in addition to its role in activating certain downstream genes, the product of *APETALA-2* represses the expression of *AGAMOUS* in whorls 1 and 2. As a result, *AGAMOUS* is normally not expressed in whorls 1 and 2. However, when *APETALA-2* is nonfunctional, *AGAMOUS* is expressed wherever *APETALA-2* would normally repress it. The result is activity C in whorls 1 and 2. Similarly, in addition to its role in activating other genes, the product of *AGAMOUS* represses the expression of *APETALA-2* in whorls 3 and 4, so *APETALA-2* is normally not expressed in whorls 3 and 4.

We can see this relationship between genes and activity, and the interaction of the activities, in the mutants in [Fig. 19.20](#). In the *APETALA-2* mutant, for example, the *APETALA-2* gene is disrupted, meaning that there is no A activity in the plant at all. Activity A normally represses the expression of *AGAMOUS* in whorls 1 and 2, so its absence means that whorl 1 (normally just activity A) expresses only activity C, leading to the development of carpels in whorl 1; and whorl 2 (normally activities A and B, with C repressed) expresses activities B and C, leading to the development of stamens in whorl 2.

The identification of the products of these genes demonstrates combinatorial control and explains the mutant phenotypes. All of the genes encode transcription factors, which are called AP2, AP3, PI, and AG, corresponding to the four genes. The transcription factors bind to cis-regulatory elements of genes that encode proteins that are necessary for each whorl's development, similar to what we saw earlier for Pax6 and eye development. AP3 and PI are both necessary for the B activity because the proteins form a heterodimer, a protein made up of two different subunits.

Although other transcription factors associated with other activities that also contribute to flower development were discovered later, the original ABC model is still valid and serves as an elegant example of combinatorial control. As in the case of the *Pax6* gene in the development of animals' eyes, evolution of the cis-regulatory sequences in downstream genes has resulted in a wide variety of floral morphologies in different plant lineages, some of which are shown in [Fig. 19.22](#).

### Self-Assessment Questions

11. How does combinatorial control work in the context of floral development?
12. What is the phenotype of a flower in which *APETALA-2* (activity A) and *AGAMOUS* (activity C) are expressed normally, but *APETALA-3* and *PISTILLATA* (activity B) are expressed in all four whorls?

## 19.5 CELL SIGNALING IN DEVELOPMENT

As we have seen in the discussion of stem cells, differentiated cells can be reprogrammed by the action of only a few key genes or small organic molecules. In some cases, the processes that push differentiation in a forward direction are also quite simple. An important example is [signal transduction](#), in which an extracellular molecule acts as a signal to activate a membrane protein that, in turn, activates molecules inside the cell that control differentiation ([Chapter 9](#)). The signaling molecule is called the [ligand](#) and the membrane protein that it activates is called the [receptor](#). The following example shows how a simple ligand–receptor pair can have profound effects not only on the differentiation of the cell that carries the receptor, but also on its neighbors.

### A signaling molecule can cause multiple responses in the cell.

Pioneering experiments on signal transduction in development were carried out in the soil nematode *Caenorhabditis elegans* ([Fig. 19.23](#)). This worm is a useful model organism for developmental studies because of its small size (the adult is about 1 mm long), short generation time (2½ days from egg to sexually mature adult), and process of development that is always the same in each individual. The adult animal consists of exactly 959 somatic (body) cells, and the cells' patterns of division, migration, differentiation, and morphogenesis are identical in each individual *C. elegans*. The adult is typically a

hermaphrodite that produces both male and female reproductive cells. The eggs are fertilized internally by sperm, and after undergoing five or six cell divisions, the eggs are laid through an organ known as the vulva ([Fig. 19.23](#)).

Vulva development is relatively simple and therefore amenable to experimental studies. The entire structure arises from only three multipotent cells that undergo either of two types of differentiation and divide to produce a vulva consisting of exactly 22 cells. Cells resulting from type 1 differentiation form the opening of the vulva, and cells resulting from type 2 differentiation form a supporting structure around the vulval opening. In each of the two types of differentiation, different genes are activated or repressed, resulting in differentiated cells with different functions.

How each of the three original cells, called progenitor cells,

differentiates is determined by its position in the developing worm ([Fig. 19.24](#)). The fates of the progenitor cells are determined by their proximity to another cell, called the anchor cell (the green cell labeled “AC” in [Fig. 19.24a](#)), which secretes a protein called epidermal growth factor (EGF) that binds to and activates a transmembrane EGF receptor ([Chapter 9](#)). The progenitor cell closest to the anchor cell receives the most amount of signal, and upon activation of its EGF receptor, the progenitor cell carries out three functions:

- It activates the genes for differentiation into a type 1 cell ([Fig. 19.24a](#)).
- It prevents the adjacent cells from differentiating as type 1 (a process called [lateral inhibition](#)).
- It induces the adjacent cells to differentiate as type 2 cells.

FIG. 19.24 Vulva development in *Caenorhabditis elegans*. The cells of the vulva differentiate in response to molecular signals from other cells.

## Developmental signals are amplified and expanded.

How can a single ligand–receptor pair cause so many changes in gene expression that it determines the pathway of differentiation not only of the cell itself but also of its neighbors? [Fig. 19.25](#) shows the mechanisms in simplified form. On the left in red is the progenitor cell

nearest the anchor cell, which receives the strongest EGF signal. Activation of the EGF receptor by the ligand initiates a process of signal transduction in the cytoplasm. The signal received by the EGF receptor is transmitted from one protein to the next by proteins at each stage phosphorylating several others, which also amplifies the signal at each stage ([Chapter 9](#)). The result of signal transduction is that a set of transcription factors is activated.

In the nucleus, the transcription factors activate transcription of genes for type 1 differentiation. The transcription factors also activate transcription of genes that prevent type 1 differentiation in neighboring cells, including the genes that produce another type of protein ligand,

called Notch. The Notch ligand is embedded in the type 1 cell's membrane and activates Notch receptors in the neighboring cells. Activation of the Notch receptor in these cells activates a signal transduction cascade in these cells, which results in transcription of the genes for type 2 differentiation. The cascade started by the binding of Notch also activates transcription of other genes whose products inhibit the EGF receptor. Inhibiting the EGF receptor in type 2 cells prevents EGF from eliciting a type 1 response in the type 2 cell. In addition, at the same time that the type 1 cell produces the Notch ligand, it produces proteins that inhibit its own Notch receptors, and this prevents Notch from initiating a type 2 response in the type 1 cell.

Although vulva development in nematodes is a fairly simple example of the importance of ligand–receptor signaling in development, EGF and Notch ligands and their receptors are found in virtually all animals. They are among dozens of ligand–receptor pairs that have evolved as signaling mechanisms to regulate processes in cellular metabolism and development. Humans have several distinct but related gene families of EGF and Notch ligands and receptors. Human EGF is important in cell survival, proliferation, and differentiation. EGF functions in the differentiation and repair of multiple types of cells in the skin; it is present in all body fluids and helps regulate rapid metabolic responses to changing conditions. Human Notch ligands are involved in development of the nervous and immune systems as well as heart, pancreas, and bone. Abnormalities in EGF or Notch signaling are associated with many different types of cancer.

Therefore, just as we saw in our discussion of eye and flower development, the molecular players involved in development are often evolutionarily conserved across a wide range of organisms. This is true even of genes that we typically associate with disease, such as *BRCA1* and *BRCA2* and their link with cancer. These genes not only play a role in cell cycle control in the adult, but also in early development in many organisms. In fact, although heterozygous mutations in these genes predispose individuals to breast and ovarian cancers in humans, homozygous mutations are lethal in early embryonic stages. In [Fig. 19.26](#), we focus on the *BRCA1* gene to summarize key concepts about DNA replication, mutation, genetic variation, inheritance, gene regulation, and development.

FIG. 19.26 VISUAL SYNTHESIS: Genetic Variation and Inheritance  
Integrating concepts from [Chapters 12–19](#)

## Self-Assessment Question

13. Diagram a pathway of signal transduction including a ligand, receptor, and ultimately a transcription factor that activates a gene that inhibits the receptor.

## CORE CONCEPTS SUMMARY

**19.1 GENETIC BASIS OF DEVELOPMENT:** In the development of humans and other animals, stem cells become progressively more restricted in their possible pathways of cellular differentiation.

The fertilized egg is totipotent, which means it can give rise to a complete organism. [page 399](#)

At each successive stage in development, cells lose developmental potential as they differentiate. [page 400](#)

Embryonic stem cells are pluripotent and can give rise to any of the three germ layers. [page 400](#)

Multipotent cells can form only a limited number of specialized cell types. [page 400](#)

Stem cells play a prominent role in regenerative medicine, in which stem cells—in some cases, reprogrammed cells from the patient's own body—are used to replace diseased or damaged tissues. [page 400](#)

**19.2 HIERARCHICAL CONTROL:** The genetic control of development is a hierarchy in which genes are activated in groups that, in turn, regulate the next set of genes.

Hierarchical gene control can be seen in fruit fly (*Drosophila*) development. [page 403](#)

The oocyte of a fruit fly is highly polarized, with gradients of maternal mRNA that set up anterior–posterior and dorsal–ventral

axes. [page 404](#)

These gradients, in turn, affect the expression of segmentation genes in the zygote, including the gap, pair-rule, and segment-polarity genes, which define specific regions in the developing embryo. [page 406](#)

The segmentation genes direct the expression of homeotic genes, which are key transcription factors that specify the identity of each segment of the fly and that are conserved in animal development. [page 407](#)

**19.3 MASTER REGULATORS:** Many master regulators that play key roles in development are evolutionarily conserved but can have dramatically different effects in different organisms.

Many proteins that are important in development are similar in sequence from one organism to the next. Such proteins are said to be evolutionarily conserved. [page 409](#)

The downstream targets of homeotic genes are different in different animals, allowing homeotic genes to activate different developmental pathways in different organisms. [page 411](#)

Although animals exhibit an enormous diversity in eye morphology, the observation that the proteins involved in light perception are evolutionarily conserved suggests that the ability to perceive light may have evolved once, early in the evolution of animals. [page 411](#)

The Pax6 transcription factor is a master regulator of eye

development. Loss-of-function mutations in *Pax6* result in abnormalities in eye development, whereas gain-of-function mutations result in eye development in tissues in which eyes do not normally form. [page 410](#)

**19.4 COMBINATORIAL CONTROL:** Combinatorial control is a developmental strategy in which cellular differentiation depends on the particular combination of transcription factors present in a cell.

By analyzing mutants that affect flower development in the plant *Arabidopsis*, researchers were able to determine the genes involved in normal flower development. [page 412](#)

The ABC model of flower development invokes three activities (A, B, and C) present in circular regions (whorls) of the developing flower, with the specific combination of factors determining the developmental pathway in each whorl. [page 412](#)

**19.5 CELL SIGNALING IN DEVELOPMENT:** Ligand–receptor interactions activate signal transduction pathways that converge on transcription factors and genes that determine cell fate.

Cell signaling involves a ligand, an extracellular molecule that acts as a signal to activate a membrane receptor protein, which, in turn, activates molecules inside the cell. [page 414](#)

Activation of a receptor sets off a pathway of signal transduction, in which a series of proteins in the cytoplasm become sequentially activated. [page 414](#)

Because signal transduction can amplify and expand a

developmental signal, a single ligand–receptor pair can cause major changes in gene expression and ultimately determine the pathway of differentiation. [page 414](#)

An example of signal transduction in development is differentiation of the nematode vulva, which is determined by means of an EGF ligand and receptor. [page 415](#)

## CASE 4

### Malaria

#### *Coevolution of Humans and a Parasite*

Most people would say the world has more than enough mosquitoes, but in 2010 scientists at the University of Arizona conjured up a new variety. The high-tech bloodsuckers were genetically engineered to resist *Plasmodium*, the single-celled eukaryote that causes malaria.

*As humans have tried a succession of ways to defeat P. falciparum, the parasite has evolved, thwarting our efforts.*

Normally, the *Plasmodium* parasite grows in the mosquito's gut and is spread to humans by the insect's bite. But by altering a single

gene in the mosquito's genome, the researchers made the insects immune to the malaria parasite. As a consequence, these mosquitoes could not spread malaria to humans. The accomplishment is a noteworthy advance, the latest in a long line of efforts to stop *Plasmodium* in its tracks.

Malaria is one of the most devastating diseases on the planet. The World Health Organization estimates that 500 million people contract malaria annually, primarily in tropical regions. The disease is thought

to claim about 1 million lives each year. Of those deaths, 85% to 90% occur in sub-Saharan Africa, mostly among children younger than 5 years of age.

Five species of *Plasmodium* can cause malaria in humans. One of them, *P. falciparum*, is particularly dangerous, accounting for the vast majority of malaria fatalities. Over thousands of years, this parasite and its human host have played a deadly game of tug-of-war. As humans have tried a succession of ways to defeat *P. falciparum*, the parasite has evolved, thwarting our efforts. In turn, the tiny organism has helped to shape human evolution.

*Plasmodium* is a wily and complicated parasite, requiring both humans and mosquitoes to complete its life cycle. The human part of the cycle begins with a single bite from an infected female mosquito. As the insect draws blood from a human, it releases *Plasmodium*-laden saliva into the human's bloodstream. Once inside their human host, the *Plasmodium* parasites invade the liver cells. There, the parasites undergo cell division for several days, so that their numbers increase. Eventually, the parasites infect red blood cells, where they continue to grow and multiply. The mature parasites burst from the red blood cells at regular intervals, triggering malaria's telltale cycle of fever and chills.

Some of the freed *Plasmodium* parasites go on to infect new red blood cells. Others divide to form gametocytes, the male and female reproductive cells, which travel through the victim's blood vessels. When another mosquito bites the infected individual, it takes up the

gametocytes with its blood meal. Inside the insect, the parasite completes its life cycle. First the gametocytes fuse to form zygotes. Those zygotes then bore into the mosquito's stomach, where they form cells called oocysts that give rise to a new generation of parasites. When the infected mosquito sets out to feed, the cycle begins again.

The battle between malaria and humankind has raged through the ages. Scientists have recovered *Plasmodium* DNA from the bodies of

3500-year-old Egyptian mummies—evidence that ancient humans were infected with the malaria parasite. The close connection between humans, mosquitoes, and the malaria parasite almost certainly extends back much further.

In fact, people who hail from regions where malaria is endemic are more likely than others to have certain genetic signatures that offer some degree of protection from the parasite. That finding indicates that *Plasmodium* has been exerting evolutionary pressure on humankind for quite some time.

Meanwhile, we've done our best to fight back. For centuries, humans have fought the infection with quinine, a chemical found in the bark of the South American *Cinchona* tree. In the 1940s, scientists developed a more sophisticated drug based on the *Cinchona* compound. That drug, chloroquine, was effective, inexpensive, easy to administer, and caused few side effects. As a result, it was widely used. Unfortunately, in the late 1950s, *P. falciparum* began showing signs of resistance to chloroquine. Within 20 years, the resistance had spread to Africa, so that today the once-potent medication is no longer effective against most strains of *P. falciparum*.

Just as bacteria develop resistance to antibiotics, *Plasmodium* evolves resistance to the antiparasitic drugs designed to fight it. In poor, rural areas where malaria is prevalent, people often can't follow the recommended protocols for antimalarial treatment. Sick individuals may be able to afford only a few pills rather than the full recommended course. The strength and quality of those pills may be questionable,

and the drugs are often taken without oversight from a medical professional.

This kind of inadequate use of the drugs fuels resistance. When pills are altered or the course of treatment is abbreviated, not all *Plasmodium* parasites are wiped out. The parasites that survive in the presence of the drug are resistant to the drug. Because these resistant parasites have a survival advantage compared to parasites that succumb to the drug, the population evolves. As a result, the genes for drug resistance spread quickly through the population.

Since chloroquine resistance has emerged among *Plasmodium* species, pharmaceutical researchers have developed a variety of new medications to prevent or treat malaria. Most, however, are far too expensive for people in the poverty-stricken regions where malaria is rampant. And just as was the case with chloroquine, almost as quickly as new drugs are developed, *Plasmodium* evolves resistance to them.

One of the newest drugs used to treat malaria is artemisinin, a compound derived from the Chinese wormwood tree. Artemisinin is an effective and relatively inexpensive way to treat malaria infections. However, pockets of artemisinin-resistant *Plasmodium* have already been uncovered in Southeast Asia. Public health workers now recommend that artemisinin be given in combination with other drugs. Treating infected patients with multiple drugs is more likely to wipe out *Plasmodium* in their bodies, reducing the chances that more drug-resistant strains will emerge.

Given the challenges of developing drugs to prevent or treat

malaria, some scientists have turned their attention to other approaches. One option is to produce a malaria vaccine. The parasite's complex life cycle makes that a complicated endeavor, though. Several vaccines are now in various stages of testing, and some show promise. Even so, researchers expect it will be years before a safe, effective vaccine for malaria could be available.

Other researchers are focusing their efforts on the mosquitoes that carry the parasite, rather than on *Plasmodium* itself. The genetically engineered insects created by the team in Arizona are a promising step in that direction.

The Arizona researchers set out to alter a cellular signaling gene that plays a role in the mosquito's life cycle. Mosquitoes normally live 2 to 3 weeks, and *Plasmodium* takes about 2 weeks to mature in the mosquito's gut. The researchers hoped to create mosquitoes that would die prematurely, before the parasite was mature. The genetic modification worked as planned: the engineered mosquitoes' life-spans were shortened by around 20%. But the genetic tweak also had a surprising side effect: the altered gene completely blocked the development of *Plasmodium* in the mosquitoes' guts. As a consequence, the engineered mosquitoes were incapable of spreading malaria to humans, regardless of how long they lived.

While the outcome of this work was a laboratory success, it will be much harder to translate the results to the real world. To create malaria-free mosquitoes in the wild, scientists would have to release the genetically modified mosquitoes and hope that their altered gene

spreads through the wild mosquito population. But that gene would be passed on only if it gave the insects a distinct evolutionary advantage. The engineered mosquitoes may be malaria free, but so far they have no advantage over their wild counterparts.

It's clear that slashing malaria rates will not be an easy task. Despite decades of research, insecticide-treated bed nets are still the best method for preventing the disease in humans. For millennia, the malaria parasite has managed to withstand human efforts to squelch it, yet science continues to push the boundaries. Who will emerge the victor? Stay tuned.

## DELVING DEEPER INTO CASE 4

**For each of the Cases, we provide a set of questions to pique your curiosity. These questions cannot be answered directly from the Case itself, but instead introduce issues that will be addressed in chapters to come. We revisit this Case in [Chapters 20–23](#) on the pages indicated below.**

1. Which genetic differences make some individuals more and some less susceptible to malaria? See [page 437](#).
  2. How did malaria come to infect humans? See [page 457](#).
  3. Which human genes are under selection for resistance to malaria? See [page 507](#).

## CHAPTER 20 Evolution

### How Genotypes and Phenotypes Change over Time

Andrew Berry

---

## CORE CONCEPTS

**20.1 GENETIC VARIATION:** Genetic variation refers to differences in DNA sequences.

**20.2 MEASURING GENETIC VARIATION:** Patterns of genetic variation can be described by allele frequencies.

**20.3 EVOLUTION AND THE HARDY–WEINBERG EQUILIBRIUM:** Evolution is a change in the frequency of alleles or genotypes in a population over time.

**20.4 NATURAL SELECTION:** Natural selection leads to adaptations, which increase the fitness of an organism to its environment.

**20.5 NON-ADAPTIVE MECHANISMS OF EVOLUTION:** Genetic drift, migration, mutation, and nonrandom mating are also mechanisms of evolution.

**20.6 MOLECULAR EVOLUTION:** Molecular evolution is a change in DNA or amino acid sequences over time.

---

A walk down any street reveals how variable our species is: skin color and hair color, for example, vary from person to person. Until the publication in 1859 of Charles Darwin's *On the Origin of Species*, scientists tended to view all the variation we see in humans and other species as biologically unimportant. According to the prevailing view at the time, not only were species individually created in their modern forms by a divine Creator, but, because the Creator had a specific design in mind for each species, they were fixed and unchanging. In keeping with this perspective, departures or variations from this

divinely ordained type were ignored.

Since Darwin, however, we have learned that a species consists of a range of variants. In our own species, we can observe that people may be tall, short, dark-haired, fair-haired, and so on. In fact, variation is an essential ingredient of Darwin's theory because the mechanism he proposed for evolution, natural selection, depends on the differential success—in terms of surviving and reproducing—of variants. Darwin changed how we view variation. Before Darwin, variation was irrelevant, something to be ignored; after Darwin, it was recognized as the key to the evolutionary process.

## 20.1 GENETIC VARIATION

Variation is a major feature of the natural world. We humans are particularly good at noticing phenotypic variation among individuals of our own species. As we discussed in [Chapter 15](#), a phenotype is an observable trait, such as human height or butterfly wing color. Recall from [Chapter 17](#) that two factors contribute to phenotype: an individual's genotype, which is the set of alleles possessed by the individual, and the environment in which the individual lives. By sequencing DNA regions in multiple individuals, we can take the environment out of the equation. Thus, this approach allows us to explore genetic variation directly by looking at differences at the DNA sequence level.

### Population genetics is the study of patterns of genetic variation.

Remarkably, in spite of a high degree of phenotypic variation, humans actually rank low in terms of overall genetic variation compared with other species. Any two randomly selected humans differ from each other, on average, by one DNA base per thousand (the two genomes are 99.9% identical), whereas two fruit flies differ by ten bases per thousand (the two genomes are 99% identical). Even one of the most seemingly uniform species on the planet, the Adélie penguins seen in [Fig. 20.1](#), is two to three times more genetically variable than humans are.

Source: Ralph Lee Hopkins/Getty Images.

FIG. 20.1 Genetic diversity in Adélie penguins. Adélie penguins are uniform in appearance but are actually more genetically diverse than humans.

As we discuss in [Chapter 21](#), a **species** is a group of individuals that are capable, through reproduction, of sharing alleles with one another. Individuals represent different combinations of alleles drawn from the species' **gene pool**, which consists of all the alleles present in all of the individuals in the species. The human gene pool includes alleles that cause differences in skin color, hair type, eye color, and so on. Each one of us has a different set of those alleles—alleles that cause brown hair and brown eyes, for example, or alleles that cause black hair and blue eyes—drawn from that gene pool.

Population genetics is the study of genetic variation in natural **populations**, which are interbreeding groups of organisms of the same species living in the same geographical area. Which factors determine the amount of variation in a population and in a species? Why are humans genetically less variable than fruit flies and Adélie penguins?

Which factors affect the distribution of particular variations?

Population genetics addresses detailed questions about patterns of variation. And small variations, given enough time, can accumulate to produce the major differences we see among species.

## Mutation and recombination are the two sources of genetic variation.

Genetic variation has two sources. First, mutation generates new variation. Second, recombination followed by segregation of homologous chromosomes during meiotic cell division shuffles mutations to create new combinations. In both cases, new alleles are formed, as shown in [Fig. 20.2](#).

FIG. 20.2 Mutation and recombination. The formation of new alleles occurs by mutation and recombination.

---

As we saw in [Chapter 14](#), mutations can be [somatic mutations](#), which occur in the body's tissues in nonreproductive cells, or [germ-line mutations](#), which occur in the reproductive cells. Germ-line mutations are passed on to the next generation, so, from an evolutionary standpoint, these are our primary focus. A somatic mutation affects only the cells descended from the one cell in which the mutation originally arose, so it affects only that one individual. In contrast, a germ-line mutation appears in every cell of an individual derived from the fertilization involving the mutation-bearing gamete, so it appears in its descendants.

We can also classify mutations by their effects on an organism ([Chapter 14](#)). Mutations occur randomly throughout the genome. Every human is born with about 60 new mutations, but, because most of the genome consists of noncoding DNA, most of these are [neutral](#) and have little or no effect. In contrast, a large proportion of those mutations that occur in protein-coding regions of the genome have a [deleterious](#) (harmful) effect on an organism. Rarely, a mutation occurs that has a beneficial effect. These kinds of mutations are [advantageous](#) if they improve their carriers' chances of survival or reproduction. Advantageous mutations, as we will see, can increase in frequency in a population until eventually they are carried by every member of a species. These mutations are the ones that result in a species that is adapted to its environment—better able to survive and reproduce in that environment.

1. Why are germ-line mutations more important in evolution than somatic ones?
2. Why is recombination critical to generating genetic variation?

Why are germ-line mutations more important in evolution than somatic ones?

## 20.2 MEASURING GENETIC VARIATION

Mutations, whether deleterious, neutral, or advantageous, are sources of genetic variation. The goal of population genetics is to make inferences about the evolutionary process from patterns of genetic variation in nature. The raw information for this comes from the rates of occurrence of alleles in populations, which population geneticists refer to as [allele frequencies](#) in populations.

To understand patterns of genetic variation, we require information about allele frequencies.

The allele frequency of an allele  $x$  is the number of  $x$ 's present in the population divided by the total number of alleles. In other words, allele frequency is the proportion, among all the alleles of a gene in a population, that consists of a specified allele. Consider, for example, pea color in Mendel's pea plants. In [Chapter 15](#), we discussed how pea color (yellow or green) results from variation at a single gene. Two alleles of this gene are the dominant  $A$  (yellow) allele and the recessive  $a$  (green) allele.  $AA$  homozygotes and  $Aa$  heterozygotes produce yellow peas, whereas  $aa$  homozygotes produce green peas. Imagine that in a population every pea plant produces green peas, meaning that only one allele,  $a$ , is present. In this population, the allele frequency of  $a$  is 100%, and the allele frequency of  $A$  is 0%. When a population exhibits only one allele at a particular gene, we say that the population is [fixed](#) for that allele. Similarly, fixation is the change from a situation where

there are at least two alleles to a situation where only one of the alleles remains.

Now consider another population of 100 pea plants with genotype frequencies of 50% *aa*, 25% *Aa*, and 25% *AA*. The **genotype frequency** is the proportion in a population of each genotype at a particular gene or set of genes. The genotype numbers for this population are 50 green pea homozygotes (*aa*), 25 yellow pea heterozygotes (*Aa*), and 25 yellow pea homozygotes (*AA*).

What is the allele frequency of *a* in this population? Each of the 50 *aa* homozygotes has two *a* alleles and each of the 25 heterozygotes has one *a* allele. There are no *a* alleles in *AA* homozygotes. The total number of *a* alleles is  $(2 \times 50) + 25 = 125$ . To determine the allele frequency of *a*, we divide the number of *a* alleles by the total number of alleles in the population, 200 (because each pea plant is diploid, meaning that it has two alleles):  $125/200 = 62.5\%$ . Because we are dealing with only two alleles in this example, the allele frequency of *A* is  $100\% - 62.5\% = 37.5\%$ .

The allele frequencies of *A* and *a* provide a measure of genetic variation at one gene in a given population. In this example, we were given the genotype frequencies, and from this information we determined the allele frequencies. But how are genotype and allele frequencies measured? In the following section, we consider three ways to measure genotype and allele frequencies in populations: observable traits, gel electrophoresis, and DNA sequencing.

## Early population geneticists relied on observable traits and gel electrophoresis to measure variation.

It would be a simple matter to measure genetic variation in a population if we could always use observable traits, as we did with the pea plant example. In that case, we could simply count the individuals displaying variant forms of a trait and have a measure of the variation of that trait's gene. However, as we saw in [Chapter 17](#), this approach works only rarely, for two important reasons. First, many traits are encoded by a large number of genes. In these cases, it is difficult, if not impossible, to make direct inferences from a phenotype to the underlying genotype. Even traits that seem to have a simple set of phenotypes often prove to have a complicated genetic basis. For instance, human skin color is determined by at least six different genes. Second, the phenotype is a product of both the genotype and the environment.

Until the 1960s, only one workable solution was available: to limit population genetics to the study of phenotypes that are encoded by a single gene. As these phenotypes are relatively rare, the number of genes that population geneticists could study was extremely small. Human blood groups, including the ABO system, provided an early example of a trait encoded by a single gene with multiple alleles. At this gene, there are three alleles in the population—*A*, *B*, and *O*—and therefore six possible genotypes, which result in four different phenotypes ([Table 20.1](#)).

TABLE 20.1 The ABO

blood system.

| PHENOTYPE | GENOTYPE               |
|-----------|------------------------|
| A         | <i>AA</i> or <i>AO</i> |
| B         | <i>BB</i> or <i>BO</i> |
| AB        | <i>AB</i>              |
| O         | <i>OO</i>              |

Other instances in which phenotypic variation can be readily correlated with genotype include certain markings in invertebrates. For example, the coloring of the two-spot ladybug *Adalia bipunctata* is controlled by a single gene ([Fig. 20.3](#)). The genetic basis of most traits, however, is not so simple.

Sources: (left) © Biopix: G Drange; (right) Howard Marsh/Shutterstock.

FIG. 20.3 Single-gene variation. A genetic difference in color in the two-spot ladybug, *Adalia bipunctata*, results from variation in a single gene.

Single-gene variation became much easier to detect in the 1960s with the application of gel electrophoresis. In [Chapter 12](#), we saw how gel electrophoresis separates segments of DNA according to their size.

Before DNA technologies were developed, the same basic process was applied to proteins to separate them according to their electrical charge and their size. In gel electrophoresis, the proteins being studied migrate through a gel when an electrical charge is applied. The rate at which the proteins move from one end of the gel to the other is determined by their charge and their size.

Early studies of protein electrophoresis focused on enzymes that catalyze reactions that can be induced to produce a dye when the substrate for the enzyme is added. If researchers add the substrate, they can see the locations of the proteins in the gel. The bands in the gel provide a visual picture of genetic variation in the population, revealing which alleles are present and what their frequencies are. [Fig. 20.4](#) shows this sort of experiment.

#### HOW DO WE KNOW?

### FIG. 20.4

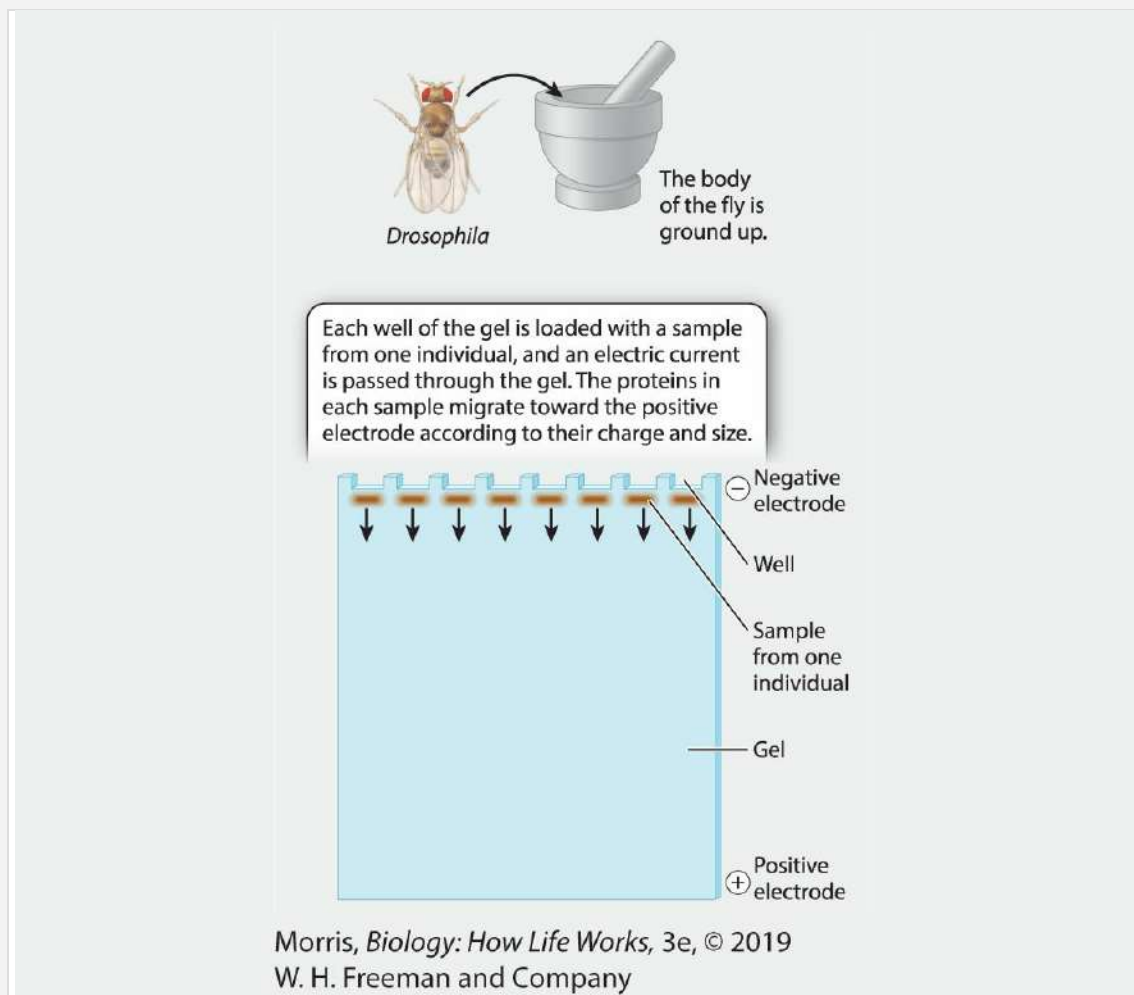

## How did gel electrophoresis allow us to detect genetic variation?

#### BACKGROUND

The introduction of protein gel electrophoresis in 1966 gave researchers the opportunity to identify differences in amino acid sequence in proteins both among individuals and, in the case of heterozygotes, within individuals. In gel electrophoresis, proteins with different amino acid sequences move at different rates through a gel in an electric field. Often, a single amino acid difference is enough to affect the mobility of a protein in a gel.

#### METHOD

Researchers load material derived from crude tissue—in this case, the ground-up whole body of a fruit fly (*Drosophila melanogaster*)—on a gel and turn on the current. The rate at which any given protein migrates depends on its size and its charge, both of which may be affected by its amino acid sequence. To visualize the protein at the end of the gel run, researchers use a biochemical indicator that produces a stain when the protein of interest is active. In the experiment shown here, researchers used a biochemical agent that detects the activity of alcohol dehydrogenase (*Adh*) as the indicator. A series of bands on the gel shows where the *Adh* proteins in each lane migrated.

## RESULTS

The *Adh* gene has two common alleles, which are distinguished by a single amino acid difference that changes the charge of the protein. One

allele, *Fast* (*F*), runs faster than the other, *Slow* (*S*). In the diagram below, the experimental results show that four individuals are *S* homozygotes, two are *F* homozygotes, and two are *FS* heterozygotes. Note that the heterozygotes do not stain as strongly on the gel because each band has half the intensity of the single band in the homozygote. We can measure the allele frequencies by counting the alleles. Each homozygote has two of the same allele, and each heterozygote has one of each.

Total number of alleles in the population of 8 individuals =  $8 \times 2 = 16$

Number of *S* alleles in the population =  $2 \times (\text{number of } S \text{ homozygotes}) + (\text{number of heterozygotes}) = 8 + 2 = 10$

$$\text{Frequency of } S = \frac{10}{16} = \frac{5}{8}$$

Number of *F* alleles in the population =  $2 \times (\text{number of } F \text{ homozygotes}) + (\text{number of heterozygotes}) = 4 + 2 = 6$

$$\text{Frequency of } F = \frac{6}{16} = \frac{3}{8}$$

Note that the two allele frequencies add to 1.

#### CONCLUSION

The experiment provides a profile of genetic variation at this gene for these eight individuals. Population genetics involves comparing data such as these with data collected from other populations to determine the forces shaping patterns of genetic variation.

#### FOLLOW-UP WORK

This technique is seldom used now because it is easy to recover much more detailed genetic information about genetic variation from DNA sequencing.

ORIGINAL PAPER Lewontin, R. C., and J. L. Hubby. 1966. "A Molecular Approach to the Study of Genic Heterozygosity in Natural Populations. II. Amount of Variation and Degree of Heterozygosity in Natural Populations of *Drosophila pseudoobscura*." *Genetics* 54:595–609.

## DNA sequencing is the gold standard for measuring genetic variation.

Protein gel electrophoresis was a leap forward in our ability to detect genetic variation, but this technique had significant limitations.

Researchers could study only enzymes because they needed to be able to stain specifically for enzyme activity. The technique also could detect only mutations that resulted in amino acid substitutions that changed a protein's mobility in the gel. Only with DNA sequencing did researchers finally have an unambiguous means of detecting all genetic variation in a stretch of DNA, whether in a coding region or not. The variations studied by modern population geneticists are differences in DNA sequence, such as a T rather than a G at a specified nucleotide position in a particular gene.

Calculating allele frequencies with DNA sequencing involves collecting a population sample and counting the number of occurrences of a given mutation. For example, researchers can look even more closely at the example of the *Drosophila Adh* gene from [Fig. 20.4](#) to focus not on the amino acid difference between the *Fast* and *Slow* phenotypes, but on the A or G nucleotide difference underlying the two phenotypes. If they sequence the *Adh* gene from 50 individual flies, they then have 100 gene sequences from these diploid individuals. If their finding is that 70 sequences have an A and 30 have a G at the position in question, the allele frequency of A is  $70/100 = 0.7$  and the allele frequency of G is 0.3. In general, in a sample of  $n$  diploid individuals, the allele frequency is the number of occurrences of that allele divided by twice the number of individuals.

#### Self-Assessment Questions

3. What is genetic variation, and how is it measured?
4. Using the example of pea color in Mendel's pea plants, devise equations to determine the allele frequencies of  $A$  and  $a$  from the genotype frequencies of  $aa$ ,  $Aa$ , and  $AA$ .
5. Data on genetic variation in populations have become ever more precise over time, from phenotypes determined by a single gene to results obtained through gel electrophoresis that looks at variation among genes that encode for enzymes, to data generated directly from the DNA sequence. Has this increase in precision resulted in the discovery of more genetic variation or less?
6. What does it mean to say that an allele is "fixed" in a population?

## 20.3 EVOLUTION AND THE HARDY–WEINBERG EQUILIBRIUM

Allele frequencies give us information about genetic variation.

Following and measuring changes in that variation over time is key to understanding the genetic basis of evolution.

### Evolution is a change in allele or genotype frequency over time.

At the genetic level, evolution is a change in the frequency of an allele or a genotype from one generation to the next. For example, if there are 200 copies of an allele that causes blue eye color in a population in generation 1 and there are 300 copies of that allele in a population of the same size in generation 2, evolution has occurred. In principle, evolution may occur without allele frequencies changing. For instance, in our fruit fly example, even if the *A/G* allele frequencies stay the same from one generation to the next, the frequencies of the different genotypes (*AA*, *AG*, and *GG*) may change. This would be evolution *without* allele frequency change.

Evolution is therefore a change in the genetic makeup of a population over time. Note an important and often misunderstood aspect of this definition: *populations* evolve, not *individuals*. Note, too, that this definition does not specify a mechanism for this change. As we will see, many mechanisms can cause allele or genotype frequencies to change. Regardless of which mechanisms are involved,

any change in allele frequencies, genotype frequencies, or both constitutes evolution.

## The Hardy–Weinberg equilibrium describes situations in which allele and genotype frequencies do not change.

Allele and genotype frequencies change over time only if specific forces act on the population. This principle, which was demonstrated independently in 1908 by the English mathematician G. H. Hardy and the German physician Wilhelm Weinberg, has become known as the **Hardy–Weinberg equilibrium**. In essence, the Hardy–Weinberg equilibrium describes the situation in which evolution does *not* occur. In the absence of evolutionary forces (such as natural selection), allele and genotype frequencies do not change.

To determine whether evolutionary forces are at work, we need to determine whether a population is in Hardy–Weinberg equilibrium. The Hardy–Weinberg equilibrium specifies the relationship between allele frequencies and genotype frequencies when several key conditions are met. In cases in which these conditions are met, we can conclude that evolutionary forces are not acting on the gene in the population we are studying. In many ways, then, the Hardy–Weinberg equilibrium is most interesting when we find instances in which allele or genotype frequencies *depart* from expectations. This finding implies that one or more of the conditions are *not* met and that evolutionary mechanisms are at work.

A population that is in Hardy–Weinberg equilibrium meets these conditions:

1. **There is no difference in the survival and reproductive success of individuals.** Let's examine what happens when this condition is *not* met. Given two alleles,  $A$  and  $a$ , consider what occurs when  $a$ , a recessive mutation, is lethal. In other words, all  $aa$  individuals die. In every generation, then, there is a selective elimination of  $a$  alleles, meaning that the frequency of  $a$  will gradually decline (and the frequency of  $A$  correspondingly increase) over the generations. As we discuss later in this chapter, we call this differential success of alleles [selection](#).
2. **The population is sufficiently large to prevent sampling errors.** Small samples are often more misleading than large ones. On a campus-wide basis, a college's sex ratio may be close to 50:50, but it is not improbable that a small class of eight individuals might consist of six women and two men (a 75:25 ratio). Sample size, in the form of population size, also affects the Hardy–Weinberg equilibrium such that it technically holds only for infinitely large populations. A change in the frequency of an allele due to the random effects of small population size is called [genetic drift](#).
3. **Populations are not added to or subtracted from by migration.** Again, let's see what happens when this condition is *not* met. Consider two populations, the first with only  $A$  alleles and the second with a mix of  $A$  and  $a$  alleles. If there is a sudden influx of individuals from the second population into the first, the frequency of  $A$  in the first population will decline in proportion to the number of immigrants as  $a$  alleles enter the population.

4. **There is no mutation.** If  $A$  alleles mutate into  $a$  alleles (or other alleles, if the gene has multiple alleles), and vice versa, then again we see changes in the allele frequencies over the generations, meaning that this condition is *not* met and evolutionary change is occurring. In general, because mutation is so rare, it has a very small effect on changing allele frequencies on the timescales studied by population geneticists.
5. **Individuals mate at random.** For a population to be in Hardy–Weinberg equilibrium, mate choice must be made without regard to genotype. For example, an  $AA$  homozygote, when offered a choice of mate from among  $AA$ ,  $Aa$ , or  $aa$  individuals, must choose at random. In contrast, **nonrandom mating** occurs when individuals do not mate randomly. For example,  $AA$  homozygotes might preferentially mate with other  $AA$  homozygotes. Nonrandom mating affects genotype frequencies from generation to generation, but does not affect allele frequencies.

## The Hardy–Weinberg equilibrium relates allele frequencies and genotype frequencies.

Now that we have established the conditions required for a population to be in Hardy–Weinberg equilibrium, let us explore the idea in detail. Let's return to the Mendel's peas example we looked at earlier where there are two alleles,  $A$  and  $a$ , determining pea color. In a different population from the one we originally looked at, we find 70  $A$  alleles and 30  $a$  alleles. What are the genotype frequencies? How many  $AA$  homozygotes,  $Aa$  heterozygotes, and  $aa$  homozygotes are there in the

population? The Hardy–Weinberg equilibrium predicts the expected genotype frequencies from allele frequencies as long as the Hardy–Weinberg conditions are met.

Recall that random mating is a condition that must be met if a population is in Hardy–Weinberg equilibrium. Random mating is the equivalent of putting all the population's gametes into a single pot and drawing out pairs of them at random to form zygotes. This is the same principle we saw in action in the discussion of independent assortment in [Chapter 15](#). If there are 70 *A* alleles and 30 *a* alleles and mating is random, what is the probability of picking an *AA* homozygote? That is, what is the probability of picking an *A* allele followed by another *A* allele?

The probability of picking an *A* allele is the same as the *A* allele's frequency in the population. Therefore, the probability of picking the first *A* is  $70/100 = 0.7$ . What is the probability of picking the second *A*? Also 0.7. The probability of picking an *A* followed by another *A* is the product of the two probabilities:  $0.7 \times 0.7 = 0.49$ . There is a 49% probability of picking an *AA* homozygote. That means that the frequency of an *AA* genotype is 0.49. We can follow the same steps to determine the genotype frequency for the *aa* genotype. Its frequency is  $0.3 \times 0.3$ , or 0.09, so there is a 9% probability of picking an *aa* homozygote.

What about the genotype frequency of the heterozygote, *Aa*? If mating is random and a population is in Hardy–Weinberg equilibrium, what is the probability of an *Aa* heterozygote? We compute this value

by determining the probability of drawing  $a$  followed by  $A$ , or  $A$  followed by  $a$ . In other words, there are two separate ways in which we can generate the heterozygote. Its frequency is therefore  $(0.7 \times 0.3) + (0.3 \times 0.7) = 0.42$ , so there is a 42% probability of picking an  $Aa$  heterozygote.

As seen in the Punnett square on the left in [Fig. 20.5](#), we can generalize these calculations algebraically by substituting letters for the numbers to derive the relation defined by the Hardy–Weinberg equilibrium. If the allele frequency of one allele,  $A$ , is  $p$ , and the other allele,  $a$ , is  $q$ , then  $p + q = 1$ . This is because there are no other alleles at this gene and allele and genotype frequencies always sum to 1 (or 100%).

|             |       |       |       |
|-------------|-------|-------|-------|
| Genotypes   | $AA$  | $Aa$  | $aa$  |
| Frequencies | $p^2$ | $2pq$ | $q^2$ |

FIG. 20.5 Hardy–Weinberg relation. The Hardy–Weinberg relation predicts genotype frequencies from allele frequencies, and vice versa.

In the graph on the right-hand side of [Fig 20.5](#), we have replaced the  $p$ 's and  $q$ 's with numbers. If no *a* alleles are present, then  $q = 0$  and  $p = 1$  and the frequency of *AA* is 1. In other words, the allele frequency of *a* is 0, the allele frequency of *A* is 1, and the genotype frequency of *AA* is 1. In this case, all the genotypes in the population are *AA*. Accordingly, the blue line representing the frequency of *AA* in the population is at 1, and the red line representing the frequency of *aa* and the purple line representing the frequency of *Aa* are both at 0. When no *A* alleles are present, all individuals have genotype *aa*, and the red line is at 1 and the blue and purple lines are at 0.

Not only does the Hardy–Weinberg relation predict genotype

frequency from allele frequencies, but it works in reverse, too: genotype frequencies predict allele frequencies. The graph in Fig. 20.5 shows how allele and genotype frequencies are related. We can use the graph to determine allele frequencies for given genotype frequencies, and genotype frequencies for given allele frequencies. For example, if the population we are examining has a 0.5 genotype frequency of heterozygotes,  $Aa$ , the purple line in the graph indicates that allele frequencies for  $p$  and  $q$  are both 0.5. Similarly, if we know that the allele frequency for  $p = 0.5$  (and therefore  $q = 0.5$ ), we can look at the lines to infer that the genotype frequency of heterozygotes is 0.5 and the genotype frequency of both homozygotes,  $AA$  and  $aa$ , is the same, 0.25.

We can do this mathematically as well. Knowing the genotype frequency of  $AA$ , for example, permits us to calculate allele frequencies: if, as in our pea example,  $p^2$  is 0.49 (that is, 49% of the population has genotype  $AA$ ), then  $p$ , the allele frequency of  $A$ , is 0.7. Because  $p + q = 1$ , then  $q$ , the allele frequency of  $a$ , is  $1 - 0.7 = 0.3$ .

Note that these relationships hold only if the Hardy–Weinberg conditions are met. If not, then allele frequencies can be determined only from genotype frequencies, as described earlier in [section 20.2](#).

## The Hardy–Weinberg equilibrium is the starting point for population genetic analysis.

Recall the definition of evolution: a change in allele or genotype

frequency from one generation to the next. Given this definition, it might seem odd that we have spent so much time discussing factors necessary for allele frequencies to stay the same. Why study the Hardy–Weinberg equilibrium at all? The Hardy–Weinberg equilibrium provides a means of converting between allele and genotype frequencies, but, critically, when it is *not* upheld, this equilibrium also serves as an indicator that something interesting is happening in a population from an evolutionary viewpoint.

When we find a population whose allele or genotype frequencies are not in Hardy–Weinberg equilibrium, we can infer that evolution has occurred in that population. With further study of the population, we can consider, for the gene in question, whether the population is subject to selection, genetic drift, migration, mutation, or nonrandom mating. These are the primary mechanisms of evolution. (Recall that the conditions of the Hardy–Weinberg equilibrium are concerned with these five mechanisms.) Thus, the Hardy–Weinberg equilibrium gives us a baseline from which to explore the evolutionary processes affecting populations. In the next section, we start our exploration by considering one of the most important evolutionary mechanisms: natural selection.

#### Self-Assessment Questions

7. Can evolution occur without allele frequency changes? If not, why not? If so, how?
8. What can and can't we conclude about a population whose allele frequencies are not in Hardy–Weinberg equilibrium?

9. How would you calculate genotype frequencies of a population in Hardy–Weinberg equilibrium, given the allele frequencies for that trait?

## 20.4 NATURAL SELECTION

Natural selection results in allele frequencies changing from generation to generation according to the allele's impact on the survival and reproduction of individuals. New mutations that are deleterious and eliminated by natural selection have no long-term evolutionary impact; in contrast, mutations that are beneficial can result in adaptation to the environment over time.

### Natural selection brings about adaptations.

The adaptations we see in the natural world—the exquisite fit of organisms to their environment—were typically taken by pre-Darwinian biologists as evidence of a divine Creator's existence. Each species, they argued, was so well adapted—the desert plant so physiologically adept at coping with minimal levels of rainfall and the fast-swimming fish so hydrodynamically streamlined—that it must have been designed by a Creator.

With the publication of *On the Origin of Species* in 1859, Darwin, pictured in [Fig. 20.6](#), overturned the biological convention of his day on two fronts. First, he showed that species are not unchanging, but rather have evolved over time. Second, he suggested a mechanism, natural selection, that brings about adaptation. Natural selection is a brilliant solution to the central problem of biology: how organisms come to fit so well in their environments. From where does the woodpecker get its powerful chisel of a bill? And the hummingbird its long delicate bill for probing the nectar stores in flowers? Darwin

showed how a simple mechanism, without foresight or intentionality, could result in the extraordinary range of adaptations that all of life is testimony to.

FIG. 20.6 Charles Darwin. This photograph was taken at about the time Darwin was writing *On the Origin of Species*.

For 20 years after first conceiving the essence of his theory, Darwin collected supporting evidence for that theory. In 1858, he was finally spurred to begin writing *On the Origin of Species* by a letter from a little-known naturalist collecting specimens in what is today Indonesia. By a remarkable coincidence, Alfred Russel Wallace, shown in [Fig.](#)

[20.7](#), had also developed the theory of evolution by natural selection. Aware that Darwin was interested in the problem but having no idea that Darwin was working on the same theory, Wallace wrote to Darwin in 1858 to ask what Darwin thought of his idea.

*Source: A. R. Wallace Memorial Fund & G. W. Beccaloni.*

FIG. 20.7 Alfred Russel Wallace. This photograph was taken in Singapore during Wallace's expedition to Southeast Asia.

Suddenly, Darwin was confronted with the prospect of losing his claim on the theory that he had been quietly nurturing for 20 years. But all was not lost. Darwin's colleagues arranged for the publication of a joint paper by Wallace and Darwin in 1858. This was done without

consulting Wallace, who nonetheless never resented Darwin and afterward was careful to insist that the idea belonged to Darwin. It was Darwin's publication of *On the Origin of Species* in 1859 that brought both evolution and natural selection, its underlying mechanism of adaptation, to public attention. Wallace is only fleetingly mentioned in Darwin's great work, and Darwin, not Wallace, is now the name associated with the discovery.

Both Darwin and Wallace recognized their debt to the writings of a British clergyman, Thomas Robert Malthus. In his *An Essay on the Principle of Population*, first published in 1798, Malthus pointed out that natural populations have the potential to increase in size geometrically, meaning that populations can grow larger at an ever-increasing rate. For example, imagine that human couples each have just four children (two males and two females), so the population doubles every generation. Starting with a single couple, by the twentieth generation, the population will have grown to more than a million people—1,048,576, to be precise.

In reality, this geometric expansion of populations does not occur. In fact, population sizes are typically stable from generation to generation, largely because the resources upon which populations depend—food, water, places to live—are limited. In each generation, many individuals fail to survive or reproduce. Put simply, there are not enough food and other resources to go around, so individuals within a population must compete for survival.

Which individuals will win the competition? Darwin and Wallace

suggested that those that are best adapted would most likely survive and leave more offspring. Genetic variation among individuals results in some individuals that are more likely than others to survive and reproduce, passing their genetic material to the next generation. As a result, the next generation has a higher proportion of these same advantageous alleles. Darwin used the term “natural selection” for the filtering process that acts against deleterious alleles and in favor of advantageous ones.

Competitive advantage is a function of how well an organism is adapted to its environment. A desert plant that is more efficient at minimizing water loss than another plant is better adapted to the desert environment. An organism that is better adapted to its environment is more fit. **Fitness**, in this context, is a measure of the extent to which the individual’s genotype is represented in the next generation. We say that the first plant’s fitness is higher than the second plant’s fitness if the former leaves more surviving offspring either because that plant itself survives for longer, giving it greater opportunity to reproduce, or because it has some other reproductive advantage, such as the ability to produce more seeds.

Assuming that the trait maintains its advantage, natural selection acts over generations to increase the overall fitness of a population. A plant population newly arrived in a desert may be poorly adapted to its environment. Over time, however, alleles that minimize water loss increase under natural selection, resulting in a population that is better adapted to the desert.

Such changes in populations take time. Indeed, borrowing from the geologists of his day, Darwin recognized that time was a critical ingredient of his theory. Geologists had put forward a view of Earth's history that argued large geological changes—like the carving of the Grand Canyon—can be explained by simple day-to-day processes operating over vast timescales. Darwin applied this worldview to biology. He recognized that small changes, such as subtle shifts in the frequencies of alleles, could add up to major changes over long enough time periods. What might seem to us to be a trivial change over the short term can, over the long term, result in substantial differences among populations.

## The Modern Synthesis combines Mendelian genetics and Darwinian evolution.

Darwinian evolution addresses the change over time of the genetic composition of populations. It is thus a genetic theory. Although Mendel published his genetic studies of pea plants in 1866, not long after *On the Origin of Species*, Darwin never saw Mendel's work, so a key component was missing from Darwin's theory.

The rediscovery of Mendel's work in 1900 unexpectedly provoked a major controversy among evolutionary biologists. Some argued that Mendel's discoveries did not apply to most genetic variation because the traits studied by Mendel were discrete, meaning that they had clear alternative states, such as either yellow or green color in peas. Most of the variation we see in natural populations, by contrast, is continuous,

meaning that variation occurs across a spectrum ([Chapter 17](#)). Human height, for example, does not come in discrete classes. People are not either 5 feet tall or 6 feet tall and of no height in between. Instead, they may be any height within a certain range.

How could the factors that controlled Mendel's discrete traits account for the continuous variation seen in natural populations? This question was answered by the English theoretician Ronald Fisher, who realized that, instead of a single gene dictating a trait like human height, several genes might contribute to the trait. He argued that extending Mendel's theory to include multiple genes per trait could account for patterns of continuous variation that we see all around us.

Fisher's insight formed the basis of a synthesis between Darwin's theory of natural selection and Mendelian genetics that was forged during the middle part of the twentieth century. The product of this [Modern Synthesis](#) is our current theory of evolution.

## Natural selection increases the frequency of advantageous mutations and decreases the frequency of deleterious mutations.

Natural selection increases the frequency of advantageous alleles, resulting in adaptation. In some cases, natural selection increases the frequency of an advantageous allele until the population is fixed for the allele (that is, 100% of the population has the allele). To start with, a new advantageous allele will exist as a single copy in a single

individual (that is, as a heterozygote). Subsequently, under the influence of natural selection, the advantageous allele can eventually replace all the other alleles in the population. Natural selection that increases the frequency of an advantageous allele is called **positive selection**.

As we have noted, most mutations to genes are deleterious. In extreme cases, they are lethal to the individuals carrying them and, therefore, are eliminated from the population. Sometimes, however, natural selection is inefficient in getting rid of a deleterious allele. Consider a recessive lethal mutation,  $b$  (that is, one that is lethal only as a homozygote,  $bb$ , and has no effect as a heterozygote,  $Bb$ ). When  $b$  first arises, all the other alleles in the population are  $B$ , which means that the first  $b$  allele that appears in the population must be paired with a  $B$  allele, resulting in a  $Bb$  heterozygote. Because natural selection does not act against heterozygotes in this case, the  $b$  allele may increase in frequency by chance alone (we discuss how this happens in the next section). Only when two  $b$  alleles come together to form a  $bb$  homozygote does natural selection act to rid the population of those two copies of the  $b$  allele. Natural selection that decreases the frequency of a deleterious allele is called **negative selection**.

Many human genetic diseases show this same pattern: the deleterious allele is rare and recessive. Because it is rare, homozygotes for it are formed only infrequently. Recall that the expected frequency of homozygotes in a population under the Hardy–Weinberg equilibrium is the square of the frequency of the allele in the population. Therefore, if the recessive lethal allele frequency is 0.01,

we expect  $0.01 \times 0.01$ , or 1 in every 10,000 individuals, to be homozygous for it. Thus, the genetic disease occurs rarely, and the allele remains in the population because it is recessive and not expressed as a heterozygote.

---

## CASE 4 MALARIA: COEVOLUTION OF HUMANS AND A PARASITE

### Which genetic differences have made some individuals more and some less susceptible to malaria?

In addition to allowing alleles to be either eliminated or fixed, natural selection can maintain an allele at some intermediate frequency between 0 and 1. This form of natural selection, called **balancing selection**, acts to maintain two or more alleles in a population. For example, consider members of a species that face different conditions depending on where they live. One allele might be favored by natural selection in a dry area, but a different allele is favored in a wet area. In the species as a whole, these two alleles are both maintained by natural selection at intermediate frequencies.

Another example of balancing selection occurs when the heterozygote's fitness is higher than that of either of the homozygotes, resulting in selection that ensures both alleles remain in the population at intermediate frequencies. This form of balancing selection is called **heterozygote advantage**. Heterozygote advantage is illustrated by

human populations in Africa affected by malaria. Because the malaria parasite spends part of its life cycle in human red blood cells, mutations in the hemoglobin molecule that affect the structure of the red blood cells can have a negative effect on the parasite. These hemoglobin mutations can reduce the severity of malarial attacks.

Two alleles of the gene for one of the subunits of hemoglobin are *A* and *S* ([Chapter 14](#)). The *A* allele codes for normal hemoglobin, resulting in fully functional, round red blood cells. The *S* allele encodes a polypeptide that differs from the *A* allele's polypeptide in just a single amino acid. This difference makes the red blood cell distort into a sickle shape and causes the disease called sickle-cell anemia.

In regions of the world with malaria, heterozygous individuals (*AS*) have an advantage over homozygous individuals (*AA* and *SS*). *AA* homozygotes lack sickle-cell anemia, but are vulnerable to malaria. *SS* homozygotes are protected against malaria, but are burdened with sickle-cell anemia. Sick-shaped red blood cells can block capillaries, which leaves people with the *SS* genotype prone to debilitating, painful, and sometimes fatal episodes resulting from capillary blockage. *AS* heterozygotes do not have severe sickling disease and have some protection from malaria. As a result, natural selection maintains both the *A* and *S* alleles in the population at intermediate frequencies.

In areas where there is no malaria, this balance is shifted. Many African-Americans who are descended from Africans upon whom natural selection operated in favor of the heterozygote still carry the *S*

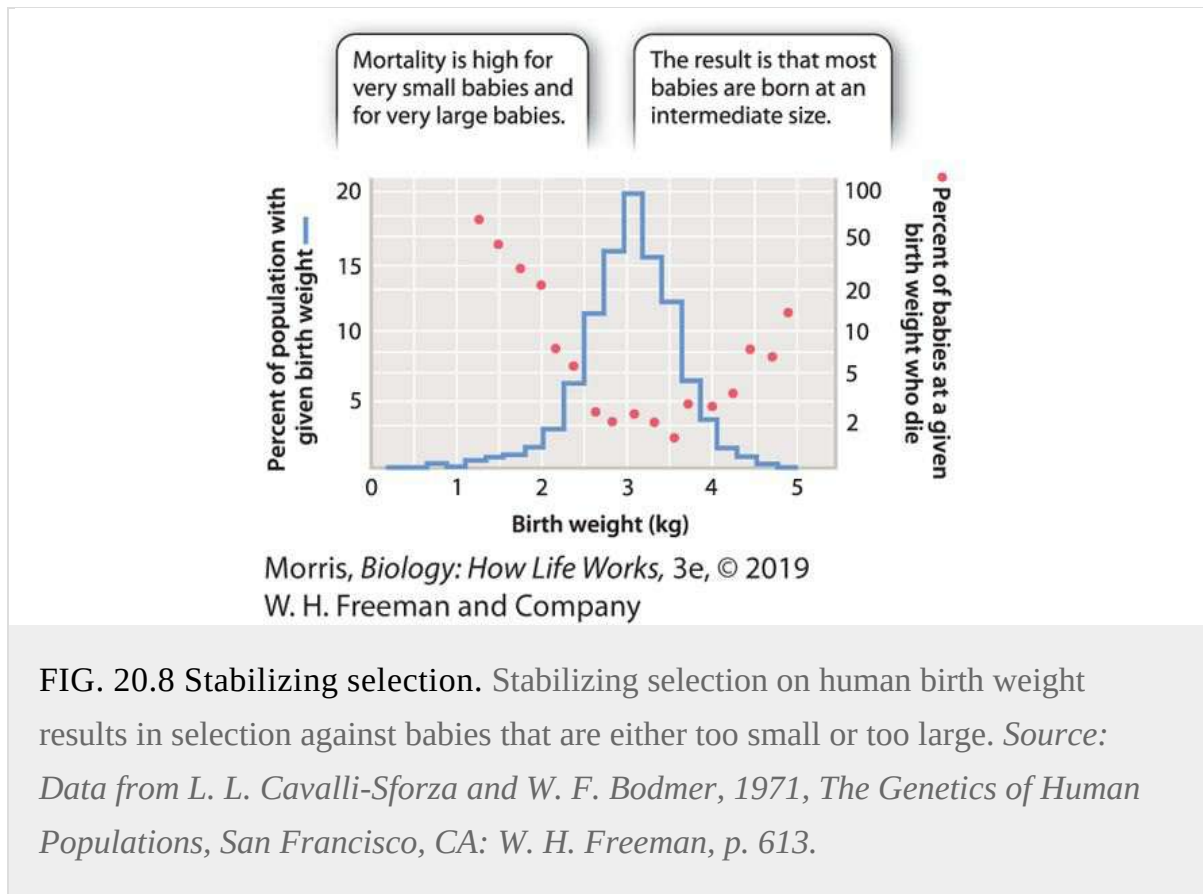

allele, even though the allele is no longer useful to them in their current malaria-free environment. If natural selection were to run its course among African-Americans, the S allele would gradually be eliminated. This is a slow process, however, and many more people will continue to suffer from sickle-cell anemia before it is complete. Fortunately, medical interventions are available that can help those affected with the disease.

## Natural selection can be stabilizing, directional, or disruptive.

Up to this point, we have followed the fate of individual mutations, which can increase, decrease, or be maintained at an intermediate frequency under the influence of natural selection. We can also look at the consequence of natural selection from a different perspective. Instead of following individual mutations, we can look at changes over time in a particular trait of an organism. For example, we might track the evolution of height in a population, despite not knowing the specifics of the genetic basis of height differences. When we look at natural selection from this perspective, we see three types of patterns: stabilizing, directional, and disruptive.

**Stabilizing selection** maintains the status quo and acts against extremes. A good example is provided by human birth weight, a trait affected by a number of factors, including many fetal genes (**Fig. 20.8**). If a baby is too small, its chances of survival after birth are low. However, if it is too big, there may be complications during delivery that endanger both mother and baby. The optimal birth weight is between these two extremes. In this case, natural selection acts against

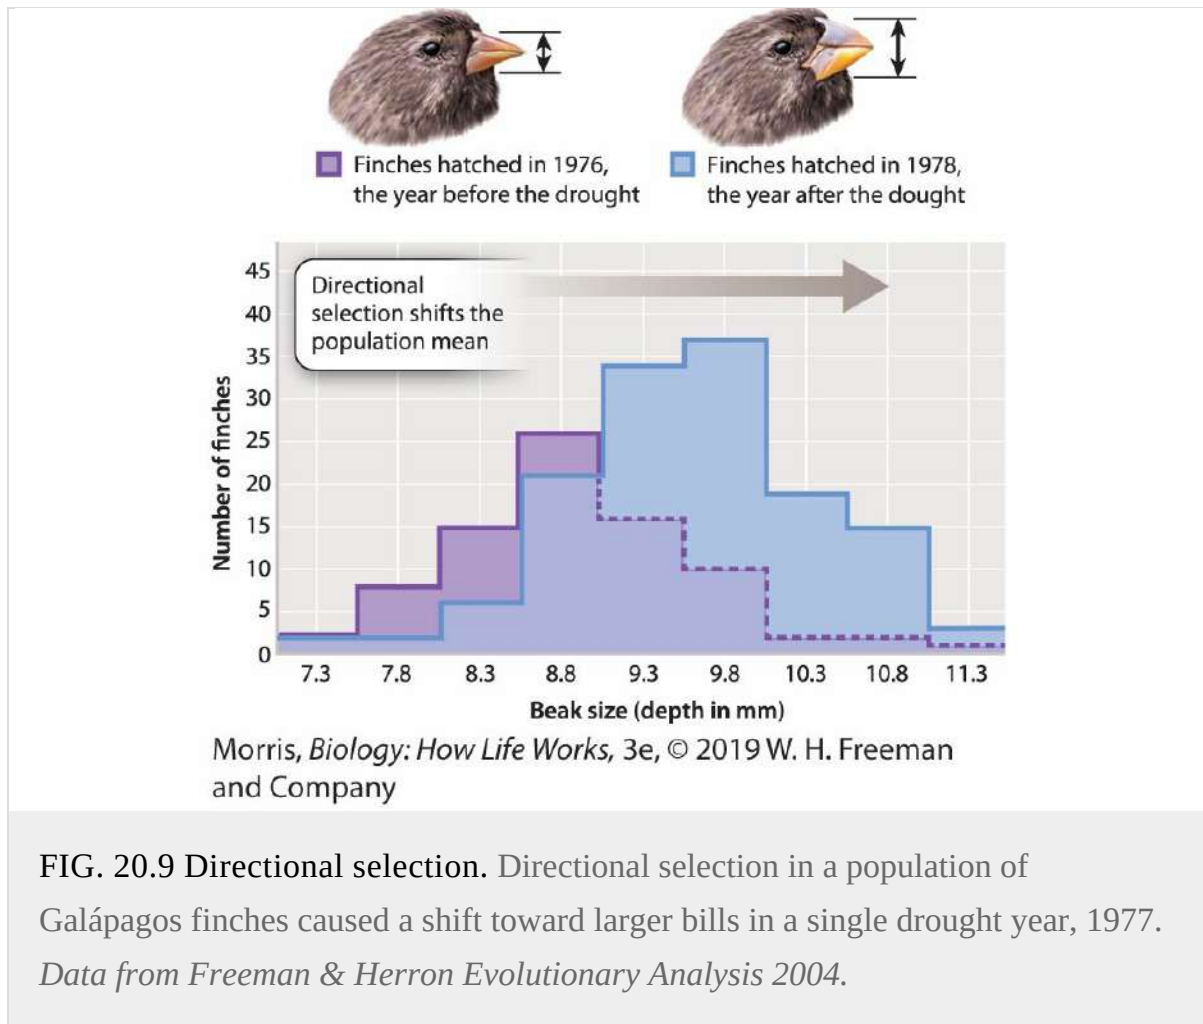

the extremes. The vast majority of natural selection is of this kind, meaning that deleterious mutations that cause a departure from the optimal phenotype are selected against.

Whereas stabilizing selection keeps a trait the same over time, **directional selection** leads to a change in a trait over time. A well-documented case of directional selection is found in Darwin's finches on the Galápagos Islands (**Fig. 20.9**). A severe drought in 1977 killed a significant amount of the vegetation that provided food for one island's population of seed-eating ground finches, *Geospiza fortis*, reducing that population's numbers from 750 to 90. Because plant species that produce big seeds fared better in drought conditions than other plant species did, the average size of seeds available to the remaining birds increased. Birds with bigger bills were better at handling the big seeds

and, therefore, had higher survival rates than birds with smaller bills. Because bill size is genetically determined, the drought resulted in directional selection for increased bill size.

**Artificial selection**, which has been practiced by humans since at least the dawn of agriculture, is a form of directional selection. Artificial selection is analogous to natural selection, but the competitive element is removed. Successful genotypes are selected by the breeder, not through competition. Because it can be carefully controlled by the breeder, artificial selection is astonishingly efficient at generating genetic change. When practiced over many generations, artificial selection can create a population in which the selected

phenotype is quite different from that of the starting population. [Fig. 20.10](#) shows the result of artificial selection for oil content in kernels of corn.

#### HOW DO WE KNOW?

### FIG. 20.10

## How far can artificial selection be taken?

#### BACKGROUND

From the 1890s to the present day, an experiment at the University of Illinois has attempted to manipulate the properties of corn. This experiment has become one of the longest-running biological experiments in history.

#### HYPOTHESIS

Researchers hypothesized that there is a limit to the extent to which a population can respond to continued directional selection.

#### EXPERIMENT

Corn was artificially selected for either high oil content or low oil content. Every generation, researchers bred together just the plants that produced corn with the highest oil content, and did the same for the plants that produced corn with the lowest oil content. Each generation, kernels showed a range of oil levels, but only the 12 kernels with the highest or the lowest oil content were used for the next generation.

#### RESULTS

In the line selected for high oil content, the percentage of oil more than quadrupled, from about 5% to more than 20%. In the line selected for low oil content, the oil content fell so close to zero that it could no longer be measured accurately, and the selection was terminated. Both selected lines are completely outside the range of any phenotype observed at the

beginning of the experiment.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

#### FOLLOW-UP WORK

Genetic analysis of the selected lines indicates that the differences in oil content are due to the effects of at least 50 genes.

SOURCE Moose, S. P., J. W. Dudley, and T. R. Rocheford. 2004. "Maize Selection Passes the Century Mark: A Unique Resource for 21st Century Genomics." *Trends in Plant Science* 9:358–364.

A third mode of selection, known as **disruptive selection**, operates in favor of extremes and against intermediate forms. Apple maggot flies of North America, *Rhagoletis pomonella*, provide an example (**Fig. 20.11**). The larvae of these flies originally fed on the fruit of hawthorn trees. However, since the introduction of apples from Europe

about 150 years ago, these flies have become pests of apples as well. Apple trees flower and produce fruit earlier every summer than hawthorns, so disruptive selection has resulted in the production of two genetically distinct groups of flies, one feeding on apple trees and the other on hawthorn trees. Disruptive selection acts against intermediates between the two groups, which would miss the peaks of both the apple and hawthorn seasons. We explore this mechanism, which can lead to the evolution of new species, in more detail in the next chapter.

## Sexual selection increases an individual's reproductive success.

Initially, Darwin was puzzled by features of organisms that seemed to reduce an individual's chances of survival. In a letter dated a few months after the publication of *The Origin*, he wrote, “The sight of a feather in a peacock's tail, whenever I gaze at it, makes me sick!” The

tail is metabolically expensive to produce; it is an advertisement to potential predators; and it is an encumbrance in any attempt to escape a predator. How could such a feature evolve under natural selection?

In his 1871 book, *The Descent of Man, and Selection in Relation to Sex*, Darwin introduced a solution to this problem. Natural selection is indeed acting to reduce the showiness and size of the peacock's tail, but another form of selection, [sexual selection](#), is acting in the opposite direction. Sexual selection promotes traits that increase an individual's access to reproductive opportunities.

Darwin recognized that this could occur in two different ways ([Fig. 20.12](#)). In one form of sexual selection, members of one sex (usually the males) compete with one another for access to the other sex (usually the females). This form is called [intrasexual selection](#), since it focuses on interactions between individuals of one sex. Because competition typically occurs among males, it is in males that we see physical traits such as large size and horns and other elaborate weaponry, as well as fighting ability. Larger, more powerful males tend to win more fights, hold larger territories, and have access to more females.

Source: (a) Kelly Funk/Getty Images; (b) Steven Kaufman/Getty Images.

FIG. 20.12 Sexual selection. (a) Intrasexual selection often involves competition between males, as in this battle between two male elk. (b) Intersexual selection often involves bright colors and displays by males to attract females, as shown by this male and female Japanese red-crowned crane.

Darwin also recognized a second form of sexual selection. In this variant, males (typically) do not fight with one another, but instead compete for the attention of the female with bright colors or advertisement displays. In this case, females choose their mates. This form of selection is called **intersexual selection**, since it focuses on interactions between males and females. The peacock's tail is thought to be the product of intersexual selection: its evolution has been driven by a female preference for ever-showier tails. In the absence of sexual selection, natural selection would act to minimize the size of the peacock's tail. Presumably, the peacocks' tails we see are a compromise, a trade-off between the conflicting demands of attracting a mate and survival.

#### Self-Assessment Questions

10. What is natural selection, and how is it different from other mechanisms of evolution?
11. Sexual selection tends to cause bigger size, more elaborate weaponry, or brighter colors in males. Is this an example of stabilizing, directional, or disruptive selection?

## 20.5 NON-ADAPTIVE MECHANISMS OF EVOLUTION

Selection is evolution's major driving force, preferentially passing on to each new generation those mutations that best fit organisms to their environments. However, natural selection is not the only evolutionary mechanism. Other mechanisms—genetic drift, migration, mutation, and nonrandom mating—can cause allele and genotype frequencies to change as well. Unlike natural selection, however, they do not lead to adaptations. In this section, we discuss each of these other evolutionary mechanisms.

### Genetic drift is a change in allele frequency due to chance.

Genetic drift is the random change in allele frequencies from generation to generation. By “random,” we mean that frequencies go up or down simply by chance.

Genetic drift dramatically affects small populations. Consider a rare allele, *A*, with a frequency of  $1/1000$ . Imagine that habitat destruction reduces the population to just one pair of individuals, one of which, by chance, is carrying *A*. The frequency of *A* in this new population is  $1/4$  (0.25) because each individual has two alleles, giving a total of four alleles. So, we see that there was a dramatic change in allele frequency, from  $1/1000$  to  $1/4$ . In addition, a marked loss of genetic variation typically occurs as much of the variation present in the original

population is not present in the surviving pair. That is, the surviving pair carries only a few of the alleles that were present in their original population.

This is an example of a population **bottleneck**, which occurs when an originally large population is reduced to just a few individuals. Genetic drift often results from population bottlenecks. A population of Galápagos tortoises that has very low levels of genetic diversity probably went through just such a bottleneck about 100,000 years ago when a volcanic eruption eliminated most of the tortoises' habitat.

Genetic drift also occurs when a few individuals start a new population, in what is called a **founder event**. Such events occur, for example, when a small number of individuals arrive on an island and colonize it. Once again, relative to the parent population, allele frequencies are randomly changed and genetic variation is lost.

Earlier, we considered the fate of beneficial and harmful mutations under the influence of natural selection. What about neutral mutations? Natural selection, by definition, does not govern the fate of neutral mutations. Consider a neutral mutation,  $m$ , which occurs in a noncoding region of DNA and, therefore, has no effect on fitness. At first, it is present in just a single heterozygous individual. What happens if that individual fails to reproduce (for reasons unrelated to  $m$ )? In this case,  $m$  is lost from the population, but not by natural selection (which does not select against  $m$ ). Rather, this change is due to random change, so it represents a case of genetic drift. Alternatively, the  $m$ -bearing individual might by chance leave many offspring (again

for reasons unrelated to  $m$ ), in which case the frequency of  $m$  increases. In principle, it is possible over a long period of time for  $m$  to become fixed in the population. At the end of the process, every member of the population is homozygous  $mm$ .

Like natural selection, genetic drift leads to allele frequency changes and, in turn, to evolution. Unlike natural selection, however, genetic drift does not lead to adaptations because the alleles whose frequencies are changing as a result of drift do not affect an individual's ability to survive or reproduce.

## Genetic drift has a large effect in small populations.

The impact of genetic drift depends on population size ([Fig. 20.13](#)). If  $m$  arises in a very small population, its frequency will change rapidly, as shown in [Fig. 20.13a](#) and [Fig. 20.13b](#). Imagine  $m$  arising in a population of just six individuals (or three pairs). Its initial frequency is 1 in 12, or about 8% (there are a total of 12 alleles because each individual is diploid). If, by chance, one pair fails to breed and the other two pairs (including the individual who is an  $Mm$  heterozygote) each produce three offspring, and all three of the  $Mm$  individual's offspring happen to inherit the  $m$  allele, then the frequency of  $m$  has increased to 3 in 12 (25%) in a single generation. Over subsequent generations,  $m$  is either fixed or eliminated. In effect, genetic drift is equivalent to a sampling error. In a small sample, extreme departures from the expected outcome are common.

a. Population size = 4

b. Population size = 4

c. Population size = 40

d. Population size = 400

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 20.13 Genetic drift. The fate of neutral mutations is governed by genetic drift, the effect of which is more extreme in small populations than in large populations.

In contrast, if the population is large, as in [Fig. 20.13c](#) and [Fig. 20.13d](#), then changes in allele frequency from generation to generation will be much smaller, typically less than 1%. A large population is analogous to a large sample size, in which we tend not to see large departures from expectation. Toss a coin 1000 times, and you will end up with approximately 500 heads. Toss a coin 5 times, and you might well end up with zero heads. In other words, in a small sample of coin tosses, we are much more likely to see departures from our 50:50 expectation than in a large sample. The same is true of genetic drift: it is likely to be much more significant in small populations than in large ones.

## Migration reduces genetic variation between populations.

**Migration** is the movement of individuals from one population to another. It results in **gene flow**, the movement of alleles from one population to another. It is relatively straightforward to see how movements of individuals and alleles can lead to changes in allele frequencies. As an example, consider two isolated island populations of rabbits, one white and the other black. Now imagine that the isolation breaks down—a bridge is built between the islands—and migration occurs. Over time, black alleles enter the white population, and vice versa, and the allele frequencies of the two populations gradually become the same.

The consequence of migration is the homogenization of populations, making them more similar to each other and reducing genetic differences between them. Because populations are often adapted to

their particular local conditions (for example, dark-skinned humans in regions of high sunlight versus fair-skinned humans in regions of low sunlight), migration may be worse than merely non-adaptive—it may be maladaptive, in that it causes a decrease in a population's average fitness. Fair-skinned people arriving in an equatorial region, for example, are at risk of sunburn and skin cancer.

## Mutation increases genetic variation.

As we saw earlier in this chapter, mutation is a rare event. As a consequence, it is generally not important as an evolutionary mechanism that leads allele frequencies to change. Even so, as we have also seen, it is the source of new alleles and the raw material on which the other forces act. Without mutation, there would be no genetic variation and no evolution. Mutation is important in the long term but typically unimportant in the short term.

## Nonrandom mating alters genotype frequencies without affecting allele frequencies.

As we saw earlier, another way that a population can evolve is through nonrandom mating. In random mating, individuals select mates without regard for genotype. In nonrandom mating, by contrast, individuals preferentially choose mates according to their genotypes. The result is that certain phenotypes increase and others decrease. Nonrandom mating just rearranges alleles already in the gene pool and, unlike migration or mutation, does not add new alleles to the population. As a result, genotype frequencies change in nonrandom mating, whereas

allele frequencies do not.

Probably the most evolutionarily significant form of nonrandom mating is inbreeding, in which mating occurs between close relatives. Inbreeding increases the frequency of homozygotes and decreases the number of heterozygotes in a population without affecting allele frequencies.

Consider a rare allele  $b$  that has a frequency of 0.001 in a population. According to the Hardy–Weinberg equilibrium, the expected frequency of  $bb$  homozygotes is  $0.001^2 = 0.000001$ . What happens to the frequency of  $bb$  homozygotes when there is inbreeding? Suppose a father with one  $b$  allele has a son and a daughter who mate incestuously and have offspring. We know that the probability that the brother inherited the allele from his father is 0.5, and the same is true for his sister. The probability that the siblings' child is homozygous  $bb$  is the probability each sibling inherited a copy from their father ( $0.5 \times 0.5$ ) multiplied by the probability that their child inherited  $b$  from both of them ( $0.5 \times 0.5$ ), or  $(0.5)^4 = 0.0625$ . Clearly, 0.0625 is a considerably higher frequency than 0.000001.

If  $b$  is a deleterious recessive mutation, it may contribute to **inbreeding depression** in the child, a reduction in the child's fitness caused by homozygosity of deleterious recessive mutations. Inbreeding depression is a major problem in conservation biology, especially when endangered species are bred in captivity in programs starting with a just a small number of individuals.

### Self-Assessment Questions

12. Why, of all the evolutionary mechanisms, is selection the only one that can result in adaptation?
13. A female lizard floats on a log to an island where she lays her previously fertilized eggs and starts a new population on the island, where there are no other lizards. How do you think the genetic variation and allele frequencies of the island population will compare to those of the mainland population? Which mechanism of evolution is at work here?

## 20.6 MOLECULAR EVOLUTION

How do DNA sequence differences arise among species? Imagine starting with two pairs of identical twins, one pair male and the other female. We place one member of each pair together on two different islands ([Fig. 20.14](#)). If we assume the islands are completely isolated from each other, what, in genetic terms, happens over time? The original pairs are the founders of the populations on each island. The genetic starting point, in each case, is exactly the same, but, over time, differences accumulate between the two populations. Mutations occur in one population that have not arisen in the other population, and vice versa.

A mutation in either population has one of three fates: it goes to fixation (either through genetic drift or through positive selection); it is maintained at intermediate frequencies (by balancing selection); or it is eliminated (either through natural selection or genetic drift). Different mutations are fixed in each population. When we come back thousands of generations later and sequence the DNA of the original identical individuals' descendants, we will find that many differences have

accumulated. The populations have diverged genetically. What we are seeing is evidence of [molecular evolution](#).

Species are the biological equivalents of islands because they, too, are isolated. They are *genetically* isolated because, by definition, members of one species cannot exchange genetic material with members of another species ([Chapter 21](#)). The amount of time that two species have been isolated from each other is the time since their most recent common ancestor. For example, humans and chimpanzees, whose most recent common ancestor lived about 6–7 million years ago, have been isolated from each other for about 6–7 million years. Mutations arose and were fixed in the human lineage over that period; mutations, usually different ones, also arose and were fixed in the chimpanzee lineage over the same period. The result is the genetic difference between humans and chimpanzees.

## The molecular clock relates the amount of sequence difference between species and the time since the species diverged.

The extent of genetic difference, or genetic divergence, between two species is a function of the time they have been genetically isolated from each other. The longer they have been apart, the greater the opportunity for mutation and fixation to occur in each population. This correlation between the time for which two species have been evolutionarily separated and the amount of genetic divergence between them is known as the [molecular clock](#).

For a clock to function properly, it not only needs to keep time, but also needs to be set. We set the clock by using dates from the fossil record. For example, in a 1967 study, Vince Sarich and Allan Wilson determined from fossils that the lineages that gave rise to the two major groups of monkeys, the Old World and New World monkeys ([Chapter 23](#)), separated about 30 million years ago. Finding that the amount of genetic divergence between humans and chimpanzees was approximately one-fifth of that between Old World and New World monkeys, they concluded that humans and chimpanzees had been separated one-fifth as long, or about 6 million years. Although this is the generally accepted number today, Sarich and Wilson's result was revolutionary at the time, when it was thought that the two species had been separated for as long as 25 million years.

## The rate of the molecular clock varies.

Molecular clocks can be useful for dating evolutionary events like the separation of humans and chimpanzees. However, because the rates of molecular clocks vary from gene to gene, clock data should be interpreted cautiously. These rate differences can be attributed largely to differences in intensity of negative selection (which results in the elimination of harmful mutations) among different genes.

The slowest molecular clock on record belongs to the histone genes, which encode the proteins around which DNA is wrapped to form chromatin ([Chapters 3](#) and [13](#)). These proteins are exceptionally similar in all organisms; only two amino acids (in a chain of about 100) distinguish plant and animal histones. Plants and animals last shared a common ancestor more than 1 billion years ago, which means, because

each evolutionary lineage is separate, that there have been at least 2 billion years of evolution since they were in genetic contact. Despite this lengthy span, the histones have hardly changed at all. Almost any amino acid change fatally disrupts the histone protein, preventing it from carrying out its proper function. Negative selection has thus been extremely effective in eliminating just about every amino acid-changing histone mutation over 2 billion years of evolution. As a consequence, the histone molecular clock is breathtakingly slow.

Other proteins are less subject to such strong negative selection. Occasional mutations may become fixed in these proteins, either through drift (if they are neutral) or through selection (if they are beneficial). An extreme case of a fast molecular clock is that associated with a **pseudogene**, a gene that is no longer functional. Because *all* mutations in a pseudogene are by definition neutral—there is no function for a mutation to disrupt, so a mutation is neither deleterious nor beneficial—we expect to see a pseudogene's molecular clock tick at a very fast rate. In the histone genes, virtually all mutations are selected against, slowing the rate of evolution; in pseudogenes, no such negative selection is operating. **Fig. 20.15** shows the varying rates of the molecular clock for different genes.

FIG. 20.15 The molecular clock. Different genes evolve at different rates because of differences in the intensity of negative selection. *Data from Fig. 20-3, p. 733, in A. J. F. Griffiths, S. R. Wessler, S. B. Carroll, and J. Doebley, 2012, Introduction to Genetic Analysis, 10th ed., New York, NY: W. H. Freeman.*

In the next chapter, we examine how genetic divergence between populations can lead to the evolution of new species.

#### Self-Assessment Question

14. How is a molecular clock used to determine the time of divergence of two species?

## CORE CONCEPTS SUMMARY

**20.1 GENETIC VARIATION:** Genetic variation refers to differences in DNA sequences.

Differences among members of a species (phenotypic variation) are the result of differences at the DNA level (genetic variation) as well as the influence of the environment. [page 427](#)

Mutation and recombination are the two sources of genetic variation, but all genetic variation ultimately comes from mutation. [page 428](#)

Mutations can be either somatic (in body tissues) or germ line (in gametes), but germ-line mutations are the only ones that can be passed on to the next generation. [page 428](#)

When a mutation occurs in a gene, it creates a new allele. [page 428](#)

Mutations can be deleterious, neutral, or advantageous. [page 429](#)

**20.2 MEASURING GENETIC VARIATION:** Patterns of genetic variation can be described by allele frequencies.

An allele frequency is the number of occurrences of a particular allele divided by the total number of all alleles of that gene in a population. [page 429](#)

In the past, population geneticists relied on observable traits determined by single genes and protein gel electrophoresis to measure genetic variation. [page 429](#)

DNA sequencing is now the standard technique for measuring genetic variation. [page 430](#)

### **20.3 EVOLUTION AND THE HARDY-WEINBERG**

**EQUILIBRIUM:** Evolution is a change in the frequency of alleles or genotypes in a population over time.

The Hardy–Weinberg equilibrium describes situations in which allele frequencies do not change. By determining whether a population is in Hardy–Weinberg equilibrium, we can determine whether evolution is occurring in a population. [page 432](#)

The Hardy–Weinberg equilibrium makes five assumptions: the population experiences no selection, no migration, no mutation, no sampling error due to small population size, and random mating. [page 432](#)

The Hardy–Weinberg equilibrium allows allele frequencies and genotype frequencies to be calculated from each other. [page 433](#)

**20.4 NATURAL SELECTION:** Natural selection leads to adaptations, which enhance the fit of an organism to its environment.

Independently conceived by Charles Darwin and Alfred Russel Wallace, natural selection is the differential reproductive success of genetic variants. [page 434](#)

Under natural selection, a harmful allele decreases in frequency and a beneficial one increases in frequency. Natural selection does not affect the frequency of neutral mutations. [page 436](#)

Natural selection can maintain alleles at intermediate frequencies

by balancing selection. [page 437](#)

Changes in phenotype show that natural selection can be stabilizing, directional, or disruptive. [page 437](#)

In artificial selection, a form of directional selection, breeders govern the selection process. [page 439](#)

Sexual selection involves the evolution of traits that increase an individual's access to members of the opposite sex. [page 439](#)

In intrasexual selection, individuals of the same sex compete with one another, resulting in traits such as large size and horns. [page 439](#)

In intersexual selection, interactions between females and males result in traits such as elaborate plumage in male birds. [page 439](#)

## **20.5 NON-ADAPTIVE MECHANISMS OF EVOLUTION:**

Genetic drift, migration, mutation, and nonrandom mating are also mechanisms of evolution.

Genetic drift is a kind of sampling error that results in allele frequency change by chance. [page 440](#)

Genetic drift acts more strongly in small populations than in large ones. [page 441](#)

Migration involves the movement of alleles between populations (gene flow) and tends to have a homogenizing effect among populations. [page 441](#)

Mutation is the ultimate source of variation, but it also can change

allele frequencies on its own. [page 442](#)

Nonrandom mating, such as inbreeding, results in an increase in homozygotes and a decrease in heterozygotes, but does not change allele frequencies. [page 442](#)

**20.6 MOLECULAR EVOLUTION:** Molecular evolution is a change in DNA or amino acid sequences over time.

The extent of sequence difference between two species is a function of the time the two species have been genetically isolated from each other. [page 442](#)

The correlation between the sequence differences among species and the time since the common ancestry of those species is known as the molecular clock. [page 443](#)

The rate of the molecular clock varies among genes because some genes are subject to more intense negative selection than others. [page 443](#)

## CHAPTER 21 Species and Speciation

Zoonar GmbH/Alamy

---

### CORE CONCEPTS

**21.1 THE BIOLOGICAL SPECIES CONCEPT:** Reproductive isolation is the key to the biological species concept.

**21.2 REPRODUCTIVE ISOLATION:** Reproductive isolation is caused

by barriers to reproduction before or after egg fertilization.

### **21.3 SPECIATION:** Speciation underlies the diversity of life on Earth.

---

Imagine for a moment a world without **speciation**, the process that produces new and distinct forms of life. Life would have originated and natural selection would have done its job of winnowing advantageous mutations from disadvantageous ones, but the planet would be inhabited by a single kind of generally adapted organism. Instead of the staggering biological diversity we see around us—current estimates suggest that between 10 and 100 million species call Earth home—there would be just a single life-form. From a biological perspective, the planet would be a decidedly dull place. Evolution is as much about speciation, the engine that generates this breathtaking biodiversity, as it is about adaptation, the result of natural selection.

# 21.1 THE BIOLOGICAL SPECIES CONCEPT

The definition of [species](#) has been a long-standing problem in biology. In *On the Origin of Species*, Darwin wrote, “No one definition has as yet satisfied all naturalists; yet every naturalist knows vaguely what he means when he speaks of a species.” The difficulty of defining species has come to be called the species problem.

Here is the problem in a nutshell: the species, as an evolutionary unit, must by definition be fluid and capable of changing, giving rise through evolution to new species. The whole point of the Darwinian revolution is that species are not fixed. How, then, can we define something that changes over time, and, by the process of speciation, even gives rise to two species from one?

## Species are reproductively isolated from other species.

We can plainly see biodiversity, but are what we call “species” real biological entities? To test whether species are real, we can examine the natural world, measure some characteristic of the different living organisms we see, and then plot these measurements on a graph. [Fig. 21.1](#) shows such a plot, graphing antenna length and wing length of three different types of butterfly. Note that the dots, representing individual organisms, fall into non-overlapping clusters. Today, we can add a molecular dimension to this kind of analysis. When we compare genomes of multiple organisms, they, too, cluster on the basis of similarity. Each cluster is a species, and the fact that the clusters are

distinct implies that species are biologically real.

The distances we see between the dots within a cluster reflect variation from one individual to the next within a species ([Chapter 20](#)). Humans are highly variable, but overall we are more similar to one another than to our most humanlike relative, the chimpanzee. On a plot such as the one in [Fig. 21.1](#), we form a messy cluster, but that cluster does not overlap with the chimpanzee cluster.

Species, then, are real biological entities, not just a convenient way to group organisms. Whether two individuals are members of the same species is a reflection of their ability (or inability) to exchange genetic material by producing fertile offspring. Consider a new advantageous mutation that appears initially in a single individual. That individual and its offspring that inherit the mutation will have a competitive

advantage over other members of the population, and the mutation will increase in frequency until it reaches 100%. Migration among populations causes the mutation to spread further until all individuals within the species have it. The mutation spreads within the species but, with some exceptions, cannot spread beyond it.

A species represents a closed gene pool, in which alleles are shared among members of that species but usually not with members of others. As a result, it is species that become extinct, and it is species that, through genetic divergence, give rise to new species.

The definition of “species” continues to be debated to this day. The most widely used and generally accepted definition of a species is known as the [biological species concept \(BSC\)](#). The BSC was described by the great evolutionary biologist Ernst Mayr (1904–2005) as follows:

Species are groups of actually or potentially interbreeding populations that are reproductively isolated from other such groups.

Let us look at this definition closely. At its heart is the idea of reproductive compatibility. Members of the same species are capable of producing offspring together, whereas members of different species are incapable of producing offspring together. In other words, members of different species are reproductively isolated from one another.

As Mayr and many others realized, however, reproductive compatibility entails more than just the ability to produce offspring.

The offspring must be fertile and, therefore, capable of passing their genes on to their own offspring. For example, although a horse and a donkey—which are two different species—can mate to produce a mule, the mule is infertile. If a hybrid offspring is infertile, then it represents a genetic dead end.

Note, too, the “actually or potentially” part of Mayr’s definition. An Asian elephant living on the island of Sri Lanka and one living in nearby India are considered members of the same species, *Elephas maximus*, even though Sri Lankan and Indian Asian elephants never have a chance to mate with each other in nature because they are geographically separated ([Fig. 21.2](#)).

The BSC is more useful in theory than

## in practice.

Species, then, are real biological entities and the BSC is the most accepted way to define them. Nevertheless, the BSC has shortcomings, the most important of which is that it can be difficult to apply. Imagine you are on a field expedition in a rain forest and you find two insects that look reasonably alike. Are they members of the same species? To use the BSC, you would need to test whether they are capable of producing fertile offspring. In practice, you probably will not have the time and resources to perform such a test. Even if you do attempt such a test, it is possible that members of the same species will not reproduce when you place them together in a laboratory setting or in your field camp. The conditions may be too unnatural for the insects to behave in a normal way. Finally, even if they do mate, you may not have time to determine whether their offspring are fertile.

Thus, we consider the BSC to be a valid framework for thinking about species, but one that is difficult to implement. As an alternative, on a day-to-day basis, biologists often use a rule of thumb called the **morphospecies concept**. Stated simply, the morphospecies concept holds that members of the same species usually look alike. For example, the shape, size, and coloration of the bald eagle make it reasonably straightforward to determine whether a bird observed in the wild is a member of the bald eagle species.

Today, the morphospecies concept has been extended to the molecular level: members of the same species usually have similar DNA sequences that are distinct from those of other species. A remarkable project called the Barcode of Life has established a

database linking DNA sequences to species. Scientists can use it to identify species from DNA alone by sequencing the relevant segment of DNA and finding the matching sequence (and therefore the species) in the Barcode of Life database. Here, at both morphological and molecular levels, we return to those biological clusters of [Fig. 21.1](#) in which members of a species fall close to one another within a single, discrete group.

Although the morphospecies concept is useful and generally applicable, it is not infallible. Members of a species may not always look alike, but instead may show different phenotypes called polymorphisms. For example, some species of birds display color differences. Sometimes, males of a species may look different from females—think of the showy peacock, which differs dramatically from the relatively drab peahen. Young can also be very different from old: caterpillars that mature into butterflies are a striking example.

As these cases suggest, members of the *same* species can look quite *different* from one another. But it is also true that members of *different* species can look quite *similar*. Some species of butterfly, for example, appear similar but have chromosomal differences that can be observed only with the aid of a microscope ([Fig. 21.3](#)). These chromosomal differences prevent the formation of interspecies hybrids, so those butterflies meet the BSC criterion—they are different species—but they do not meet the morphospecies criterion because they look so much alike.

A direct view through the microscope of chromosomes that have been stained so they can be counted.

Morris, *Biology: How Life Works*, 3e, © 2019

W. H. Freeman and Company

Photos source: Vladimir Lukhtanov, Zoological Institute  
of Russian Academy of Sciences,  
St. Petersburg, Russia.

FIG. 21.3 Three species of *Agrodiaetus* butterflies. These similar-appearing butterflies are identifiable only by differences in their chromosome numbers.

With the application of ever more powerful DNA-based approaches to studies of natural populations, scientists frequently uncover what are called cryptic species. These species consist of organisms that had been traditionally considered as belonging to a single species because they look similar, but turn out to belong to two species because of differences at the DNA sequence level.

## The BSC does not apply to asexual or extinct organisms.

In addition to the difficulties of putting the BSC into practice, a second problem is that it overlooks some organisms. For example, because it is based on the sexual exchange of genetic information, the BSC cannot apply to species that reproduce asexually, such as bacteria. Although some asexual species do occasionally exchange genetic information in a process known as conjugation ([Chapter 24](#)), true asexual organisms do not fit the BSC.

Furthermore, because it depends on reproduction, the BSC obviously cannot be applied to species that are extinct and known only through the fossil record, such as different “species” of trilobites and dinosaurs.

## Hybridization complicates the BSC.

Populations of one species may vary in the extent to which they are reproductively isolated from a closely related species. In one location, the two groups may be reproductively isolated from each other, while, in another location, they interbreed to produce [hybrid offspring](#).

Under the BSC, the first pair of populations represents two species, whereas the second pair represents just one. A classic example is shown in [Fig. 21.4](#). Two closely related birds, called towhees, co-occur in various locations in Mexico. In some places they interbreed; in others they do not.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 21.4 Hybridization in towhee species. Two species of closely related birds (*Pipilo maculatus* and *Pipilo ocai*) overlap in places in their distributions in central Mexico. In some locations, they hybridize; in others, they do not. Source: Futuyma, *Evolution*, 2005 Sinauer.

This kind of incomplete reproductive isolation seems to be especially common in plants. Despite apparently being good morphospecies that can be distinguished by appearance alone, many different species of willow (*Salix*), oak (*Quercus*), and dandelion (*Taraxacum*) are still capable of exchanging genes with other species in their genera through [hybridization](#). According to the BSC, these different forms should be considered one large species because they are able to reproduce and produce fertile offspring. However, because the

species maintain their distinct appearances, it appears that natural selection must work against the hybrid offspring.

With the application of modern comparative genomic approaches, we are discovering that the boundaries between many closely related species are also not as strictly drawn as traditionally supposed. For example, discussed in [Chapter 23](#), our own species, *Homo sapiens*, interbred in the past with another species, *Homo neanderthalensis*.

## Ecology and evolution can extend the BSC.

To remedy these problems with the application of the BSC, much work has been put into modifying and improving the BSC and many alternative definitions of species have been suggested. In general, these efforts highlight how difficult it is to make all species fit easily into one definition. The natural world truly defies neat categorization!

Even so, several useful ideas have come out of this literature. One of these is the notion that a species can sometimes be characterized by its ecological [niche](#). A species' ecological niche (which we will discuss further in [Chapter 45](#)) is a complete description of the role the species plays in its environment—its habitat requirements, its nutritional and water needs, and the like. It turns out that it is impossible for two species to coexist in the same location if their niches are too similar because competition between them for resources inevitably leads to the extinction of one species. This observation has given rise to the [ecological species concept \(ESC\)](#), the idea that there is a one-to-one correspondence between a species and its niche.

Applying this concept, we can determine whether asexual bacterial lineages are distinct species on the basis of differences or similarities in their ecological requirements. If two lineages have very different nutritional needs, for example, we can infer on ecological grounds that they are separate species.

Another species concept is the [phylogenetic species concept \(PSC\)](#), which emphasizes that members of a species all share a common ancestry and a common fate. It is, after all, species rather than individuals that become extinct. The PSC requires that all members of a species be descended from a single common ancestor, but does not specify on what scale this idea should be applied. All mammals derive from a single common ancestor that lived approximately 200 million years ago, but there are thousands of what we recognize as species of mammals that have evolved since that long-ago common ancestor. Under a strict application of the PSC, would we consider all mammals to be a single species? Similarly, in human families, siblings and cousins are all descended from a common ancestor, a grandmother, but that is surely not sufficient grounds to classify more-distant relatives as a distinct species. The PSC can be useful when thinking about asexual species, but, given the arbitrariness of the decisions involved in assessing whether the descendants of a single ancestor warrant the term “species,” its utility is limited.

It is worth bearing these ecological and phylogenetic considerations in mind when thinking about species. Although the BSC remains our most useful definition of species, the ESC and PSC broaden and generalize the concept. For example, in the case of a normally asexual

species that is difficult to study because conjugation is so infrequent, we can jointly apply the ESC and PSC. That is, we can use the ESC to loosely define the species in terms of its ecological characteristics (for example, its nutritional requirements), and we can refine that definition by using genetic analyses to determine whether the group is indeed a species by the PSC's standard (that is, all its members derive from a single common ancestor).

Despite the shortcomings of the BSC and the usefulness of alternative ideas, we stress that the BSC is the most constructive way to think about species. In particular, by focusing on reproductive isolation—the inability of different species to produce viable, fertile offspring—the BSC gives us a means of studying and understanding speciation, the process by which two populations, originally members of the same species, become distinct.

#### Self-Assessment Questions

1. Why has the scientific community been unable to come up with a single, comprehensive, and agreed-upon concept of a “species”?
2. How is the term “species” defined according to the biological species concept (BSC)?
3. Given a group of organisms, how would you test whether they all belong to one species or whether they belong to two separate species according to the morphospecies concept?
4. Which types of organisms do not fit easily into the biological species concept? Which species concept would work best for these organisms?

5. Why do morphospecies typically correspond to BSC-defined species?

## 21.2 REPRODUCTIVE ISOLATION

Factors that cause reproductive isolation are generally divided into two categories, depending on when they act. **Pre-zygotic** isolating factors act before the fertilization of an egg, and **post-zygotic** isolating factors come into play after fertilization. In other words, pre-zygotic factors prevent fertilization from taking place, whereas post-zygotic factors result in the failure of the fertilized egg to develop into a fertile individual.

### Pre-zygotic isolating factors occur before egg fertilization.

Most species are reproductively isolated by pre-zygotic isolating factors, which can take many forms. Among animals, species are often **behaviorally isolated**, meaning that individuals mate only with other individuals based on specific courtship rituals, songs, or other behaviors. Chimpanzees may be humans' closest relative—and therefore the species we are most likely to confuse with our own—but a chimpanzee of the appropriate sex, however attractive to a chimpanzee of the opposite sex, fails to provoke even the faintest reproductive impulse in a human. In this case, the pre-zygotic reproductive isolation of humans and chimpanzees is behavioral.

Behavior does not play a role in plants, but pre-zygotic factors can still be important in their reproductive isolation. Pre-zygotic isolation in plants can take the form of incompatibility between the incoming pollen and the receiving flower, such that fertilization fails to take

place. We see similar forms of isolation between members of marine species, such as abalone, which simply discharge their gametes into the water. In these cases, membrane-associated proteins on the surface of sperm interact specifically with membrane-associated proteins on the surface of eggs of the same species, but not with those of different species. These specific interactions ensure that a sperm from one abalone species, *Haliotis rufescens*, fertilizes only an egg of its own species and not an egg from *H. corrugata*, a closely related species. Incompatibilities between the gametes of two different species is called **gametic isolation**.

In some animals, especially insects, incompatibility arises earlier in the reproductive process. As an example, the genitalia of males of the fruit fly *Drosophila melanogaster* are configured in such a way that they fit only with the genitalia of females of the same species. Thus, attempts by males of *D. melanogaster* to copulate with females of another species of fruit fly, *D. virilis*, are prevented by **mechanical incompatibility**.

Both plants and animals may also be pre-zygotically isolated in time (**temporal isolation**). For example, closely related plant species may flower at different times of the year, so there is no chance that the pollen of one species will come into contact with the flowers of the other. Similarly, members of a nocturnal animal species are unlikely to encounter members of closely related species that are active only during the day.

Plants and animals can also be isolated in space (**geographic** or

**ecological isolation**). This type of isolation can be subtle. For example, the two Japanese species of ladybug beetle shown in **Fig. 21.5** can be found living side by side in the same field, but they feed on different plants. Because their life cycles are so intimately associated with their host plants (adults even mate on their host plants), these two species never breed with each other. This ecological separation is what leads to their pre-zygotic isolation.

## Post-zygotic isolating factors occur after egg fertilization.

Post-zygotic isolating factors involve mechanisms that come into play after fertilization of the egg. Typically, they involve some kind of **genetic incompatibility**. One example, which we saw earlier in **Fig. 21.3** and will explore later in the chapter, is the case of two organisms with different numbers of chromosomes.

In some instances, the effect can be extreme. For example, the

zygote may fail to develop after fertilization because the two parental genomes are sufficiently different to prevent normal development. In others, the effect is less obvious. Some matings between different species produce perfectly viable adults, as in the case of the horse–donkey hybrid, the mule. As we have seen, though, all is not well with the mule from an evolutionary perspective. Because horses and donkeys have different chromosome numbers (haploid complements of 32 and 31, respectively), proper homologous chromosome pairing in meiosis in the mule cannot take place ([Chapter 11](#)), resulting in infertility of the mule. As a general rule, the more closely related—and therefore genetically similar—a pair of species, the less extreme the genetic incompatibility between their genomes.

#### Self-Assessment Questions

6. What is an example of a pre-zygotic isolating factor?
7. What is an example of a post-zygotic isolating factor?

## 21.3 SPECIATION

Recognizing that species are groups of individuals that are reproductively isolated from other such groups, we are now in a position to recast the key question addressed in this chapter. That is, instead of asking, “How do new species arise?” we can ask, “How does reproductive isolation arise between populations?”

### Speciation is a by-product of the genetic divergence of separated populations.

The key to speciation is the fundamental evolutionary process of genetic divergence between genetically separated populations. As we saw in [Chapter 20](#), if a single population is split into two populations that are isolated from each other, different mutations appear by chance in the two populations. Like all mutations, these are subject to genetic drift or natural selection (or both), resulting over time in the genetic divergence of the two populations. Two separate populations that are initially identical will, over long periods of time, gradually become distinct as different mutations are introduced, propagated, and fixed in each population. At some stage in the course of divergence, changes occur in one population that lead to its members becoming reproductively isolated from members of the other population ([Fig. 21.6](#)). It is this process that results in speciation.

FIG. 21.6 Speciation. Speciation occurs when two populations that are genetically diverging become reproductively isolated from each other.

Speciation—the development of reproductive isolation between populations—is, therefore, typically just a by-product of the genetic divergence of separated populations. As [Fig. 21.6](#) shows, it is typically a gradual process. If we try to cross members of two populations that have genetically diverged but not yet diverged far enough for full reproductive isolation (that is, speciation) to have arisen, we may find that the populations are **partially reproductively isolated**. In other words, they are not truly separate species, but the genetic differences between them are extensive enough that the hybrid offspring they produce have reduced fertility or viability compared to offspring produced by crosses between individuals within each population.

**Allopatric speciation is speciation that**

## results from the geographical separation of populations.

As just noted, speciation is the process by which two groups of organisms become reproductively isolated from each other. Because this process requires genetic isolation between the diverging populations and because geography is the easiest way to ensure physical and therefore genetic isolation, many models of speciation focus on geography.

The process usually begins with the creation of **allopatric** (literally, “different place”) populations, which are geographically separated from each other. Clearly, physical separation does not immediately cause reproductive isolation. If a single population is split in two by a geographic barrier, and, after a few generations, individuals from each population are allowed to interbreed again, they are still capable of producing fertile offspring and, therefore, are members of the same species. In addition to separation, the other requirement for speciation to occur is time. Time allows for different mutations to become fixed in the two separated populations so that eventually the two populations become reproductively isolated from each other.

Because genetic divergence is typically gradual, we often find allopatric populations that have yet to evolve even partial reproductive isolation but that have accumulated a few population-specific traits. This genetic distinctness is sometimes recognized by taxonomists, who call each geographic form a **subspecies** and add a further designation after its species name. For example, Sri Lankan Asian elephants, subspecies *Elephas maximus maximus*, are generally larger and darker

than their Indian counterparts, subspecies *Elephas maximus indicus* (see [Fig. 21.2](#)).

## Dispersal and vicariance can isolate populations from each other.

There are two ways in which populations may become allopatric. The first is by [dispersal](#), in which some individuals colonize a distant place, such as an island, far from the main source population. The second is by [vicariance](#), in which a geographic barrier arises within a single population, separating it into two or more isolated populations. For example, when sea levels rose at the end of the most recent ice age, new islands formed along coastlines as the low-lying land around them was flooded. The populations on those new islands suddenly found themselves isolated from other populations of their species. This kind of island formation is a vicariance event. Regardless of how the allopatric populations came about—whether through dispersal or vicariance—the outcome is the same: the two separated populations diverge genetically until speciation occurs.

Often, vicariance-derived speciation is the easier to study because we can date the time at which the populations were separated if we know when the vicariance occurred. One such event whose history is well known is the formation of the Isthmus of Panama between Central and South America, shown in [Fig. 21.7](#). This event took place approximately 3.5 million years ago. In its wake, populations of marine organisms in the western Caribbean and eastern Pacific that had formerly been able to interbreed freely were separated from each other. The result was the formation of many distinct species, with each one's

closest relative being on the other side of the isthmus.

HOW DO WE KNOW?

## FIG. 21.7

### Can vicariance cause speciation?

#### BACKGROUND

Three and a half million years ago, the Isthmus of Panama was not completely formed (top map). Several marine corridors remained open, allowing interbreeding between marine populations in the Caribbean and the eastern Pacific. Subsequently, the gaps in the isthmus were plugged, separating the Caribbean and eastern Pacific populations and preventing gene flow between them (bottom map).

W. H. Freeman and Company

### HYPOTHESIS

In 1993, American marine biologist Nancy Knowlton and her colleagues hypothesized that patterns of speciation would reflect the impact of the vicariance resulting from the closing of the direct marine connections between the Pacific and the Caribbean. Specifically, they predicted that each ancestor species (from the time before the formation of the isthmus) split into two “daughter” species, one in the Caribbean and the other in the Pacific. The closest relative of each current Pacific species, then, is predicted to be a Caribbean species, and vice versa.

### EXPERIMENT

This study focused on 17 species of snapping shrimp in the genus *Alpheus*, a group that is distributed on both sides of the isthmus. The first step was to sequence the same segment of DNA from each species. The next step was to compare those sequences so as to reconstruct the phylogenetic relationships among the species.

## RESULTS

The phylogeny reveals that species show a distinctly paired pattern of relatedness: the closest relative of each species is one from the other side of the isthmus.

## CONCLUSION

That we see these consistent Pacific/Caribbean sister species pairings strongly supports the hypothesis that the vicariance caused by the formation of the Isthmus of Panama has driven speciation in *Alpheus*. Each Pacific/Caribbean pairing is derived from a single ancestral species (indicated by a yellow dot in the phylogeny) whose continuous distribution between the Caribbean and eastern Pacific was disrupted by the formation of the isthmus. Here, we see striking evidence of the role of vicariance in multiple speciation events.

## FOLLOW-UP WORK

Speciation is about more than just genetic differences between isolated populations, as shown here. Knowlton and colleagues also tested the different species for reproductive isolation and found that there were high levels of isolation between Caribbean/Pacific pairs. Given that we know each species pair has been separated for at least 3 million years, we can

use this information to calibrate the rate at which new species are produced.

SOURCE Knowlton, N., et al. 1993. "Divergence in Proteins, Mitochondrial DNA, and Reproductive Compatibility Across the Isthmus of Panama." *Science* 260 (5114):1629–1632.

Dispersal is important in a specific kind of allopatric speciation known as **peripatric speciation** (that is, in a peripheral place). In this model, a few individuals from a **mainland population** (the central population of a species) disperse to a new location remote from the original population and evolve separately. This may be an intentional act of dispersal, such as young mammals migrating away from where they were raised, or it could be an accident brought about by, for example, an unusual storm that blows migrating birds off their normal route. The result is a distant, isolated **island population**.

"Island" in this case may refer to a true island—such as Hawaii—or may simply refer to a patch of habitat on the mainland that is appropriate for the species but is geographically remote from the mainland population's habitat area. For a species adapted to life on mountaintops, a new island might be another previously uninhabited mountaintop. For a rain forest tree species, that new island might be a patch of lowland forest on the far side of a range of mountains that separates it from its mainland forest population.

The island population is classically small and often resides in an environment that is slightly different from that of the mainland population. The peripatric speciation model suggests that change

accumulates faster in these peripheral isolated populations than in the large mainland populations for two reasons. First, genetic drift is more pronounced in smaller populations than in larger ones. Second, the environment may differ between the mainland and the island in a way that results in natural selection driving differences between the two populations. Together, these two mechanisms cause genetic divergence of the island population from the mainland one, ultimately leading to speciation.

It is possible to glimpse peripatric differentiation in action ([Fig. 21.8](#)). Studies of a kingfisher, *Tanysiptera galatea*, in New Guinea and nearby islands show the process under way. There are eight recognized subspecies of *T. galatea*: three on mainland New Guinea (where they exist in large populations separated by mountain ranges) and five on nearby islands (where, because the islands are small, the populations are correspondingly small). The mainland subspecies are still quite similar to one another, but the island subspecies are much more distinct, suggesting that genetic divergence is occurring faster in the small island populations. If we wait long enough, these subspecies will probably diverge into new species.

Because dating such dispersal events is tricky—newcomers on an island tend not to leave a record of when they arrived—we can sometimes use vicariance information to study the timing of peripatric speciation. For instance, consider the finches of the Galápagos Islands made famous by Charles Darwin. We know that the oldest of the Galápagos Islands were formed 4–5 million years ago by volcanic action. Some time early in the history of the Galápagos, individuals of a small South American bird species arrived there. Conditions on the Galápagos are very different from those on the South American continent, where the mainland population of this ancestral finch lived, so the isolated island population evolved to become distinct from its mainland ancestor and eventually became a new species.

The finches' subsequent dispersal among the other islands of the Galápagos promoted further peripatric speciation ([Fig. 21.9](#)). In the graph at the bottom of [Fig. 21.9](#), we see that the number of finch species is correlated with the number of islands in the archipelago. This is clear indication of the importance of geographic separation (allopatry) in speciation: the availability of islands provided opportunities for populations to become isolated from one another, allowing speciation. The result was the evolution of 13 different species of finches, collectively known today as Darwin's finches.

FIG. 21.9 Adaptive radiation in Darwin's finches. Today, there are 13 different species of Darwin's finches. Source: Phylogenetic tree data from Fig. 2.1, p. 15, finch species plot data from Fig. 2.4, p. 23, in P. R. Grant and B. R. Grant, 2008, *How and Why Species Multiply*, Princeton, NJ: Princeton University Press.

The Galápagos finches and their frenzy of speciation illustrate the important evolutionary idea of [adaptive radiation](#), a bout of unusually rapid evolutionary diversification in which natural selection accelerates the rates of both speciation and adaptation. Adaptive radiation occurs when an environment offers many ecological opportunities for exploitation. Consider the finch ancestor immigrants arriving on the Galápagos. A wealth of ecological opportunities were open and available to them. Until the arrival of the colonizing immigrant birds, there were no birds on the islands to eat the plant seeds, or to eat the insects on the plants, and so on. Suppose that the finch ancestors fed specifically on medium-sized seeds on the South American mainland; that is, they were medium-seed specialists, with bills that are the right size for handling medium-sized seeds. On the mainland, they were constrained to that size of seed because any attempt to eat larger or smaller seeds brought them into conflict with other species—a large-seed specialist and a small-seed specialist—that already used these resources. In effect, stabilizing selection ([Chapter 20](#)) was operating on the mainland to eliminate the extremes of the bill-size spectrum in the medium-seed specialists.

When the medium-billed immigrants first arrived on the Galápagos, however, no such competition existed. Therefore, natural selection promoted the formation of new species of small- and large-seed specialists from the original medium-seed-eating ancestral stock. With the elimination of the stabilizing selection that had kept the medium-billed birds medium-billed on the mainland, selection operated in the opposite direction, favoring the large and small extremes of the bill-size spectrum because these individuals could take advantage of the

abundance of unused resources, consisting of small and large seeds. It is this combination of emptiness—the availability of ecological opportunity—and the potential for allopatric speciation that results in adaptive radiation.

## Co-speciation is speciation that occurs in response to speciation in another species.

As we have seen, physical separation is often a critical ingredient in speciation. Two populations that are not fully separated from each other—that is, gene flow exists between them—will typically not diverge from each other genetically, because genetic exchange homogenizes them. This is why most speciation is allopatric. Although allopatric speciation brings to mind populations separated from each other by stretches of ocean or deserts or mountain ranges, separation can be just as complete in the absence of such geographic barriers.

Consider an organism that parasitizes a single host species. Suppose that the host undergoes speciation, producing two daughter species. The original parasite population is also split into two populations, one for each host species. Thus, the two new parasite populations are physically separated from each other and diverge genetically, ultimately undergoing speciation. This divergence results in a pattern of coordinated host–parasite speciation called **co-speciation**, a process in which two groups of organisms speciate in response to each other and at the same time.

The phylogenetic trees of parasites and their hosts that undergo co-speciation are similar for each group. Each time a branching event—that is, speciation—occurs in one lineage, a corresponding branching event occurs in the other ([Fig. 21.10](#)).

FIG. 21.10 Co-speciation. Parasites and their hosts often evolve together, and the result is similar phylogenies. Source: Data from J. P. Huelsenbeck and B. Rannala, 1997, “Phylogenetic Methods Come of Age: Testing Hypotheses in an Evolutionary Context,” *Science* 276:227, doi: 10.1126/science.276.5310.227.

## CASE 4 MALARIA: COEVOLUTION OF HUMANS AND A PARASITE

### How did malaria come to infect humans?

Let’s consider a human parasite, *Plasmodium falciparum*, the single-celled eukaryote that causes malaria. It had been suggested that *P. falciparum*’s closest relative is another *Plasmodium* species, *P. reichenowi*, found in chimpanzees, our closest living relative. Were *P. falciparum* and *P. reichenowi* the products of co-speciation? When the ancestral population split millions of years ago to give rise to the

human and chimpanzee lineages, that population's parasitic *Plasmodium* population could also have been split, ultimately yielding *P. falciparum* and *P. reichenowi*.

Recent studies, however, have disproved this hypothesis. We now know that *P. falciparum* was introduced to humans relatively recently from gorillas. Why doesn't the evolutionary history of *Plasmodium* follow the classical host–parasite co-speciation pattern? This history is complex and is still being unraveled. Moreover, the mosquito-borne phase of the parasite's life cycle facilitates its transfer to new hosts. Malaria parasites are not inextricably tied to their hosts, so their evolutionary history does not parallel that of their hosts as closely as the evolutionary history of the chewing lice follows that of their pocket gopher hosts.

## Sympatric populations—those in the same place—may undergo speciation.

Can speciation occur without complete physical separation of populations? The answer to this question is “yes,” although evolutionary biologists are still exploring how common this phenomenon is. Recall how separated populations inevitably diverge genetically over time (see [Fig. 21.6](#)). If a mutation arises in population A after it has separated from population B, that mutation is present only in population A. It may eventually become fixed in that population, either through natural selection, if it is advantageous, or through drift, if it is neutral. Once the mutation is fixed in population A, it represents a genetic difference between populations A and B. Repeated independent fixations of different mutations in the two

populations result over time in the genetic divergence of separated populations.

Now imagine that populations A and B are not completely separated, such that there is some gene flow between them. The mutation that arose in population A can, in principle, appear in population B as members of the two populations interbreed. Gene flow effectively negates the genetic divergence of populations. If there is gene flow, a pair of populations may change over time, but they do so together. How, then, can speciation occur if gene flow exists? The term we use to describe populations that are in the same geographic location is **sympatric** (literally, “same place”). So we can rephrase the question in technical terms: how can speciation occur sympatrically?

For speciation to occur sympatrically, natural selection must act strongly to counteract the homogenizing effect of gene flow. Consider two sympatric populations of finch-like birds, represented in the graph in **Fig. 21.11**. One population begins to specialize in feeding on small seeds and the other in feeding on large seeds. If the two populations freely interbreed, no genetic differences between the two occur, and speciation does not take place. Now suppose that the offspring produced by the pairing of a big-seed specialist with a small-seed specialist is an individual best adapted to eat medium seeds, and there are no medium-sized seeds available in the environment. Natural selection acts against the hybrids, which starve to death because there are no medium-sized seeds for them to eat and they are not well adapted to compete with the big- or small-seed specialists. Natural selection, in effect, eliminates the products of gene flow. So, although

gene flow is occurring, it does not affect the divergence of the two populations because the hybrid individuals do not survive to reproduce. As discussed in [Chapter 20](#), this form of natural selection, which operates against the middle of a spectrum of variation, is called disruptive selection.

It turns out to be difficult to find evidence of sympatric speciation in nature, though it may not be especially rare in plants, as we will see. We might find two very closely related species in the same location and argue that they must have arisen through sympatric speciation, but there is an alternative explanation. One species could have arisen elsewhere by, for example, peripatric speciation and subsequently

moved into the environment of the other species. In other words, the speciation occurred in the past by allopatry, and the two species are only currently sympatric because migration after speciation occurred.

However, recent studies of plants on an isolated island have provided strong, if not definite, evidence of sympatric speciation. Lord Howe Island is a tiny island (about 10 km long and 2 km across at its widest) located approximately 600 km east of Australia. Two species of palm tree that are found only on this island are each other's closest relatives. Because the island is so small, there is little chance that the two species could be geographically separated from each other, meaning that the species are and were sympatric. Moreover, because of the distance between Lord Howe Island and Australia (or other islands), it is extremely likely that the palms evolved and speciated from a common ancestor on the island.

This and other evidence show that sympatric speciation can occur. We must recognize, however, that we do not yet know just how much of all speciation is sympatric and how much is allopatric. [Fig. 21.12](#) summarizes modes of speciation based on geography.

FIG. 21.12 Modes of speciation.

## Speciation can occur instantaneously.

Although speciation is typically a lengthy process, it can occasionally occur in a single generation, making it sympatric by definition.

Typically, cases of such **instantaneous speciation** are caused by hybridization between two species in which the offspring are reproductively isolated from both parents.

For example, hybridization in the past between two sunflower species, *Helianthus annuus* and *H. petiolaris* (the ancestor of the cultivated sunflower), has apparently given rise to three new sunflower species: *H. anomalus*, *H. paradoxus*, and *H. deserticola* (**Fig. 21.13**). *H. petiolaris* and *H. annuus* have probably formed innumerable hybrids in nature, virtually all of them inviable. However, a few hybrids—the ones with a workable genetic complement—survived to yield these three daughter species. Each of these new species acquired

a different mix of parental chromosomes. It is this species-specific chromosome complement that makes all three distinct and reproductively isolated from the parent species and from one another.

FIG. 21.13 Speciation by hybridization. In sunflowers, *Helianthus anomalus* (bottom) is the product of natural hybridization between *H. annuus* (top left) and *H. petiolaris* (top right).

In many cases of hybridization, chromosome numbers change in the offspring compared to the parents. Two diploid parent species with 5 pairs of chromosomes, for a total of 10 chromosomes each, may produce a hybrid with double the number of chromosomes (that is, the hybrid inherits a full paired set of chromosomes from each parental

species)—a total of 20. In this case, the hybrid has 4 genomes rather than the diploid number of 2. We call such a double diploid a tetraploid. In general, animals cannot sustain this kind of expansion in chromosome complement, but plants are more likely to do so. As a result, the formation of new species through polyploidy—multiple chromosome sets ([Chapter 13](#))—has been relatively common in plants.

Polyploids may be allopolyploids, meaning that they are produced from hybridization of two different species. For example, related species of *Chrysanthemum* appear, on the basis of their chromosome numbers, to be allopolyploids. Alternatively, polyploids may be autopolyploids, meaning that they are derived from an unusual reproductive event between members of a single species. In this case, through an error of meiosis in one or both parents in which homologous chromosomes fail to separate, a gamete may be produced that is not haploid. For example, *Anemone rivularis*, a plant in the buttercup family, has 16 chromosomes, and its close relative *A. quinquefolia* has 32 chromosomes. *Anemone quinquefolia* appears to be an autopolyploid derived from the joining of *A. rivularis* gametes with two full sets of chromosomes each.

So rampant is speciation by polyploidy in plants that it affects the pattern of chromosome numbers across all plants. In [Fig. 21.14](#), the haploid chromosome numbers of thousands of plant species are plotted on a graph. Note that as the numbers get higher, even numbers tend to predominate, suggesting that the doubling of the total number of chromosomes (a form of polyploidy that always results in an even number of chromosomes) is an important factor in plant evolution.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 21.14 Plant chromosome numbers. Plant chromosome numbers suggest that polyploidy has played an important role in plant evolution. Data from Fig. 20-18, p. 752, in A. J. F. Griffiths, S. R. Wessler, S. B. Carroll, and J. Doebley, 2012, *Introduction to Genetic Analysis*, 10th ed., New York, NY: W. H. Freeman.

Do we ever see instantaneous speciation *without* changes in chromosome complement? Analysis of Darwin's finches in the Galápagos Islands suggests that hybridization between closely related species may occasionally result in new species ([Fig. 21.15](#)). Detailed study of a population of *Geospiza fortis* on one small island, Daphne Major, allowed scientists to identify a hybridization event between a resident *G. fortis* female and an incoming male *G. conirostris* from another island, Española, 100 km away. Remarkably, the offspring of this pairing were able to breed to produce a population that is reproductively isolated from Daphne Major's resident *G. fortis*.

Critically, the bill dimensions of the new species are different from those of other *Geospiza* species, so the new species can specialize on food resources not readily accessed by other species. Undoubtedly this was a rare and unusual event, but, given the vast periods of time over which the evolutionary process unspools, perhaps freak events such as this one play an important role in the generation of new species.

## Speciation can occur with or without natural selection.

The association of both the origin of species and natural selection with Charles Darwin may make it seem that one cannot occur without the other. In reality, speciation can occur in the presence or absence of natural selection, and natural selection does not always lead to speciation. The genetic divergence of two populations can be entirely due to genetic drift, for example, with no role for natural selection.

We have also seen two ways in which natural selection can be involved in speciation. First, sympatric speciation requires some form of disruptive selection, as when hybrid offspring are competitively inferior to nonhybrid offspring. Second, allopatric speciation (and adaptive radiation) may be facilitated by natural selection. For example, when a peripheral population enters a new environment, natural selection can act to promote its adaptation to the new conditions, accelerating the rate of genetic divergence between it and its parent population.

**Fig. 21.16** summarizes the evolutionary mechanisms that lead to speciation. Speciation is caused by the accumulation of genetic differences between populations. Mutation is therefore a key component of the process, but so, too, is the fixation process. (Recall

from [Chapter 20](#) that fixation is the change from a situation where there are at least two variants of a particular allele present in a population to a situation where only one of the alleles remains.) A mutation can be fixed either by selection, if it is advantageous, or by genetic drift, if it is neutral. Multiple forces acting over long periods on each population produce the differences that accumulate between diverging populations.

FIG. 21.16 VISUAL SYNTHESIS: Speciation Integrating concepts from [Chapters 20](#) and [21](#)

### Self-Assessment Questions

8. How are genetic divergence and reproductive isolation related to each other?
9. What is the difference between allopatric and sympatric speciation, and which is thought to be more common? Explain why.

10. What is the difference between allopatric speciation by dispersal and allopatric speciation by vicariance? Give an example of each.
11. Why are there so many examples of adaptive radiation on mid-ocean volcanic archipelagos such as the Galápagos?
12. There are hundreds of species of cichlid fish in Lake Victoria in Africa. Some scientists argue that they evolved sympatrically, but recent studies of the lake suggest that it periodically dried out, leaving a series of small ponds. How is this observation relevant to evaluating the hypothesis that these species arose by sympatric speciation?

## CORE CONCEPTS SUMMARY

**21.1 THE BIOLOGICAL SPECIES CONCEPT:** Reproductive isolation is the key to the biological species concept.

The biological species concept (BSC) states that species are groups of actually or potentially interbreeding populations that are reproductively isolated from other such groups. [page 448](#)

The BSC does not apply to asexual or extinct organisms. [page 449](#)

Hybridization among closely related species further demonstrates that the BSC is not a comprehensive definition of species. [page 449](#)

The BSC is nevertheless especially useful because it emphasizes reproductive isolation, and therefore provides studies of speciation with a focus. [page 450](#)

**21.2 REPRODUCTIVE ISOLATION:** Reproductive isolation is caused by barriers to reproduction before or after egg fertilization.

Reproductive barriers can be pre-zygotic, occurring before egg fertilization, or post-zygotic, occurring after egg fertilization. [page 451](#)

Pre-zygotic isolation may be behavioral, gametic, temporal, or ecological. [page 451](#)

In post-zygotic isolation, mating occurs but genetic incompatibilities prevent the development of viable, fertile offspring. [page 452](#)

**21.3 SPECIATION:** Speciation underlies the diversity of life on

Earth.

Speciation is typically a by-product of genetic divergence that occurs as a result of the fixation of different mutations in two populations that are not regularly exchanging genes. [page 452](#)

If divergence continues long enough, chance differences will arise that result in reproductive barriers between the two populations. [page 452](#)

Most speciation is thought to be allopatric, involving two geographically separated populations. [page 452](#)

Geographic separation may be caused by dispersal, resulting in the establishment of a new and distant population, or by vicariance, in which the range of a species is split by a change in the environment. [page 453](#)

A special case of allopatric speciation by dispersal is peripatric speciation, in which the new population is small and outside the species' original range. [page 453](#)

Adaptive radiation, in which speciation occurs rapidly to generate a variety of ecologically diverse forms, is best documented on oceanic islands following the arrival of a single ancestral species. [page 457](#)

Co-speciation occurs when one species undergoes speciation in response to speciation in another species. In parasites and their hosts, co-speciation can result in phylogenies that have the same branching patterns. [page 457](#)

Speciation may be sympatric, meaning that there is no geographic separation between the diverging populations. [page 458](#)

Sympatric speciation can occur by hybridization or by disruptive selection against intermediate forms that is strong enough to offset the homogenizing effect of gene flow. [page 460](#)

Separated populations can diverge as a result of genetic drift, natural selection, or both. [page 461](#)

## CHAPTER 22 Evolutionary Patterns

### Phylogeny and Fossils

Dudley Museums Service

---

## CORE CONCEPTS

**22.1 READING A PHYLOGENETIC TREE:** A phylogenetic tree is a hypothesis of the evolutionary relationships among organisms.

**22.2 BUILDING A PHYLOGENETIC TREE:** A phylogenetic tree is built on the basis of shared derived characters.

**22.3 THE FOSSIL RECORD:** The fossil record provides direct evidence of evolutionary history.

**22.4 COMPARING EVOLUTION’S TWO GREAT PATTERNS:**

Phylogeny and fossils provide independent and corroborating evidence of evolution.

---

All around us, nature displays nested patterns of similarity among species. For example, as noted in [Chapter 1](#), humans are more similar to chimpanzees than either humans or chimpanzees are to monkeys. Humans, chimpanzees, and monkeys, in turn, are more similar to one another than any one of them is to a mouse. And humans, chimpanzees, monkeys, and mice are more similar to one another than any of them is to a catfish. This pattern of nested similarity was recognized more than 200 years ago and used by the Swedish naturalist Carolus Linnaeus to classify biological diversity. A century later, Charles Darwin recognized this pattern as the expected outcome of a process of “descent with modification,” or evolution.

Evolution produces two distinct but related patterns, both evident in nature. First is the nested pattern of similarities found among species on the present-day Earth. The second is the historical pattern of evolution recorded by fossils. Life, in its simplest form, originated more than 3.5 billion years ago. Today, an estimated 10 million species inhabit the planet. Short of inventing a time machine, how can we reconstruct those 3.5 billion years of evolutionary history so as to

understand the extraordinary series of events that have ultimately resulted in the biological diversity we see around us today? These two great patterns provide the answer.

Darwin recognized that the species he observed must be the modified descendants of earlier species. Distinct populations of an ancestral species separate and diverge through time, again and again, giving rise to multiple descendant species through the processes we explored in [Chapters 20](#) and [21](#). The result is the pattern of nested similarities observed in nature. This history of descent with branching is called a [phylogeny](#), and is much like the genealogy that records our own family histories.

The evolutionary changes inferred from patterns of relatedness among present-day species make predictions about the historical pattern of evolution we should see in the fossil record. For example, groups with features that we infer to have evolved earlier than others should appear earlier in time as fossils. Paleontological research reveals that the history of life is, indeed, laid out in the chronological order predicted on the basis of comparative biology. How do we reconstruct the history of life from evolution's two great patterns, and how do they compare?

## 22.1 READING A PHYLOGENETIC TREE

[Chapter 21](#) introduced the concept of speciation, the set of processes by which physically, physiologically, or ecologically isolated populations diverge from one another to the point where they can no longer produce fertile offspring. As illustrated in [Fig. 22.1](#), speciation can be thought of as a process of branching. Now consider what happens as this process occurs over and over in a group through time. As species proliferate, their evolutionary relationships unfold in a treelike pattern, with individual species at the twig tips and their closest relatives connected to them at the nearest fork in the branch, called a **[node](#)**. Thus, a node represents the most recent common ancestor of two descendant species.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 22.1 The relationship between speciation and a phylogenetic tree. The phylogenetic tree, on the right, depicts the evolutionary relationships that result from the two successive speciation events diagrammed on the left.

## Phylogenetic trees provide hypotheses of evolutionary relationships.

Phylogenetics is one of two related disciplines within systematics, the study of evolutionary relationships among organisms. The other is taxonomy, the classification of organisms.

The aim of taxonomy is to recognize and name groups of individuals as species, and then to group closely related species into the more inclusive taxonomic group of the genus, and so on up through the

taxonomic ranks—species, genus, family, order, class, phylum, kingdom, domain. Taxonomy, then, provides us with a hierarchical classification of species in groups that are more and more inclusive, giving us a convenient way to communicate information about the features each group possesses. For example, if we want to tell someone about a small animal we have seen that has fur, mammary glands, and extended finger bones that permit it to fly, we can provide this long description. Alternatively, we can just say we saw a bat, or a member of Order Chiroptera. All the rest is understood (or can be looked up).

Phylogenetics, by contrast, aims to discover the pattern of evolutionary relatedness among groups of species or other groups by comparing their anatomical or molecular features, and to depict these relationships as a [phylogenetic tree](#). A phylogenetic tree is a hypothesis about the evolutionary history, or phylogeny, of the species. Phylogenetic trees are hypotheses because they represent the best model, or explanation, of the relatedness of organisms on the basis of the existing data. As with any model or hypothesis, the discovery of new evidence may suggest alternative relationships, leading to changes in the hypothesized pattern of branching on the tree. In recent years, biologists have worked to integrate phylogenetic branching patterns with taxonomic classification.

Many phylogenetic trees explore the relatedness of particular groups of individuals, populations, or species. We may, for example, want to understand how wheat is related to other, noncommercial grasses, or how disease-causing populations of *Escherichia coli* relate to more benign strains of the bacterium. At a much larger scale, universal

similarities of molecular biology indicate that all living organisms are descended from a single common ancestor. This insight has inspired the goal of reconstructing phylogenetic relationships for all species as a means to understand how biological diversity has evolved since life originated. This universal tree is commonly referred to as the tree of life ([Chapter 1](#)). In [Part 2](#) of this book, we will make use of the tree of life and many smaller-scale phylogenetic trees to understand our planet's biological diversity.

[Fig. 22.2](#) shows a phylogenetic tree for vertebrate animals. The informal name at the end of each branch represents a group of organisms, many of them familiar. We sometimes find it useful to refer to groups of species this way (for example, “frogs,” or “Class Anura”), rather than name all the individual species or list the characteristics they have in common. Remember, though, that such named groups represent a number of member species. If, for example, we could zoom in on the branch labeled “Frogs,” we would see that it consists of many smaller branches, each representing a distinct species of frog, either living or extinct.

This tree provides information about evolutionary relationships among vertebrates. For example, it proposes that the closest living relatives of birds are crocodiles and alligators. The tree also proposes that the closest relatives of all tetrapod (four-legged) vertebrates are lungfish, which are fish with lobed limbs and the ability to breathe air. Phylogenetic trees are built from careful analyses of the morphological features (the organism's form) and molecular attributes of the species or other groups under study. In essence, a tree is a hypothesis about the order of branching events in evolution, and that hypothesis can be

tested by gathering more information about anatomical and molecular traits.

A phylogenetic tree does not in any way imply that more recently evolved groups are more advanced than groups that arose earlier. A modern lungfish, for example, is not more primitive or “less evolved” than an alligator, even though its group branches off the trunk of the vertebrate tree from an earlier node than the alligator group does. After all, both species are the end products of the same interval of evolution since their divergence from a common ancestor more than 370 million years ago.

## The search for sister groups lies at the heart of phylogenetics.

Two species, or groups of species, are considered to be closest relatives if they share a common ancestor not shared by any other species or group. [Fig. 22.2](#), for example, illustrates that frogs are more closely related to salamanders than to any other group of organisms because frogs and salamanders share a common amphibian ancestor not shared by any other group. Similarly, lungfish are more closely related to tetrapods than to any other group. A lungfish may look more like a fish than it does an amphibian, but lungfish are more closely related to amphibians than they are to other fishes because lungfish share a common ancestor with amphibians (and other tetrapods) that was more recent than their common ancestor with other fishes ([Fig. 22.2](#)).

Groups that are more closely related to each other than either of them is to any other group, like lungfish and tetrapods, are called [\*\*sister\*\*](#)

**groups.** Simply put, phylogenetic hypotheses amount to determining sister-group relationships because the simplest phylogenetic question we can ask is which two of any three species (or other groups) are more closely related to each other than either is to the third. In this light, we can see that a phylogenetic tree is simply a set of sister-group relationships; adding a species to the tree entails finding its sister group in the tree.

Closeness of relationship is determined by checking how recently two groups shared a common ancestor. Shared ancestry is indicated by a node, or branch point, on a phylogenetic tree. Branches, in turn, can be rotated around a node without changing the evolutionary relationships of the groups. **Fig. 22.3** shows four phylogenetic trees depicting evolutionary relationships among birds, crocodiles and alligators, and turtles. In all four trees, birds are a sister group to crocodiles and alligators because birds, crocodiles, and alligators share a common ancestor that is not shared by turtles. The more recent a common ancestor, the more closely related two groups are. Evolutionary relatedness, then, is determined by following nodes from the tips to the root of the tree, rather than by the order of the tips from the top to bottom of a page or across a page.

## A monophyletic group consists of a common ancestor and all its descendants.

Up to this point, we have used the word “group” to mean all the species in some taxonomic entity, such as a genus or family. A more technical word for “group” is **taxon** (plural, **taxa**), with *taxonomy* providing a formal means of naming groups. Modern taxonomic classifications emphasize groups that are **monophyletic**, meaning that all members share a single common ancestor that is not shared with any other species or group of species. In [Fig. 22.2](#), the tetrapods are monophyletic because all of the groups classified as tetrapods share a common ancestor not shared by any other taxa. Similarly, amphibians are monophyletic.

In contrast, consider the group of animals traditionally recognized as reptiles, which includes turtles, snakes, lizards, crocodiles, and alligators ([Fig. 22.2](#)). Birds are not considered reptiles, although they share a common ancestor with the included animals. The group “reptiles” is **paraphyletic**, meaning that it includes some, but not all, of the descendants of a common ancestor. Early zoologists did not recognize the existence of a common ancestor of birds and reptiles because birds are so distinctive. Nevertheless, many features of skeletal anatomy and DNA sequence strongly support the placement of birds as a sister group to the crocodiles and alligators.

There is a simple way to distinguish between monophyletic and paraphyletic groups, illustrated in [Fig. 22.4](#). If to separate a group from

the rest of the phylogenetic tree, you need to make only one cut, the group is monophyletic (blue in [Fig. 22.4](#)). If you need to make a second cut to trim away part of the separated branch, the group is paraphyletic (green in [Fig. 22.4](#)).

FIG. 22.4 Monophyletic, paraphyletic, and polyphyletic groups. Only monophyletic groups reflect evolutionary relationships because only they include all the descendants of a common ancestor.

Groupings that do not include the last common ancestor of all

members are called **polyphyletic**. Members of a polyphyletic group share traits that evolved independently by convergent evolution. For example, clustering bats and birds together as flying tetrapods results in a polyphyletic group (red in [Fig. 22.4](#)) because wings evolved independently in the two groups and their common ancestor did not have wings.

Identifying monophyletic groups is a major goal of phylogenetics because monophyletic groups include all descendants of a common ancestor and only the descendants of that common ancestor. As a consequence, monophyletic groups alone show the evolutionary path a given group has taken since its origin. Omitting some members of a group, as in the case of reptiles and other paraphyletic groups, can provide a misleading sense of evolutionary history. By using monophyletic groups in taxonomic classification, we effectively convey our knowledge of their evolutionary history.

## Taxonomic classifications are information storage and retrieval systems.

The nested pattern of similarities among species has been recognized by naturalists for centuries. In the vocabulary of formal classification, closely related species are grouped into a **genus** (plural, **genera**). Closely related genera, in turn, belong to a larger, more inclusive branch of the tree, known as a **family**. Closely related families form an order, orders form a **class**, classes form a **phylum** (plural, **phyla**), and phyla form a **kingdom**, with each more inclusive taxonomic level

occupying a successively larger limb on the tree ([Fig. 22.5](#)). Biologists today commonly refer to the three largest limbs of the entire tree of life as [domains](#) (Eukarya, or eukaryotes; Bacteria; and Archaea).

The ranks of classification form a nested hierarchy, but the boundaries of ranks above the species level are arbitrary. Put simply, there is nothing particular about a group that makes it, for example, a class rather than an order. A taxonomist examining the 17 species included in [Fig. 22.5](#) might decide that species 3 and 4 are sufficiently distinct from species 5 to warrant placing them into a distinct genus. The same taxonomist might then decide that the grouping of the two

new genera together should rank as a family. For this reason, it is not necessarily true that orders or classes of, for example, birds and ferns are equivalent in any meaningful way. In contrast, sister groups are equivalent in several ways. Notably, they diverged from a single ancestor at a single point in time. Therefore, if one branch is a sister group that contains 500 species and another branch has 6 species, the branches have experienced different rates of speciation, extinction, or both since they diverged. In [Fig 22.5](#), Families 1 and 2 are sister groups, but Family 1 has five species while Family 2 has just one.

#### Self-Assessment Questions

1. In [Fig. 22.3](#), why does the phylogeny indicate that birds and crocodiles are more closely related to each other than either is to turtles? On the phylogeny, label the common ancestor of crocodiles and birds, and the common ancestor of turtles, crocodiles, and birds.
2. Does either of the following phylogenetic trees indicate that humans are more closely related to lizards than to mice?

3. Look at [Fig. 22.2](#). Are fish a monophyletic group?
4. In [Fig 22.2](#), hagfish and lampreys (jawless fishes) are at the top of the tree and mammals at the bottom. Does this imply that jawless fishes are less evolved than mammals?

---

## 22.2 BUILDING A PHYLOGENETIC TREE

Up to this point, we have focused on how to interpret a phylogenetic tree, a diagram that depicts the evolutionary history of organisms. But how do we infer evolutionary history from a group of organisms? That is, how do we actually construct a phylogenetic tree? Biologists use characteristics of organisms to figure out their relationships.

Similarities among organisms are particularly important, in that similarities sometimes suggest shared ancestry. However, a key principle of constructing trees is that only some similarities can actually tell us anything about a species' relationship to other species. Other shared characteristics can, in fact, be misleading.

### Homology is similarity by common descent.

Phylogenetic trees are constructed by comparing character states shared among different groups of organisms. **Characters** are the anatomical, physiological, or molecular features that make up organisms. In general, characters have several observed conditions, called **character states**. In the simplest case, a character can be present or absent. For example, lungs are present in tetrapods and lungfish, but absent in other vertebrate animals. More commonly, there are multiple character states. Petals are a character of flowers, for example, and each observed arrangement—petals arranged in a helical pattern, petals arranged in a whorl, or petals fused into a tube—can be considered a state of the character of petal arrangement. All species contain some

character states that are shared with other members of their group, some that are shared with members of other groups, and some that are unique.

Character states in different species can be similar for one of two reasons. First, the character state (for example, helically arranged petals) may have been present in the common ancestor of the two groups and retained over time (common ancestry). Alternatively, the character state may have evolved independently in the two groups as an adaptation to similar environments (convergent evolution, discussed earlier).

Consider two examples. Mammals and birds both produce amniotic eggs. Amniotic eggs occur only in groups descended from the common ancestor at the node connecting the mammal and sauropsid branches of the tree. Thus, we reason that birds and mammals each inherited this character from a common ancestor in which the trait first evolved ([Fig. 22.6](#)). The other sauropsids inherited this trait from the same common ancestor. Characters that are similar because of descent from a common ancestor are said to be [homologous](#), or a [homology](#) among descendant species.

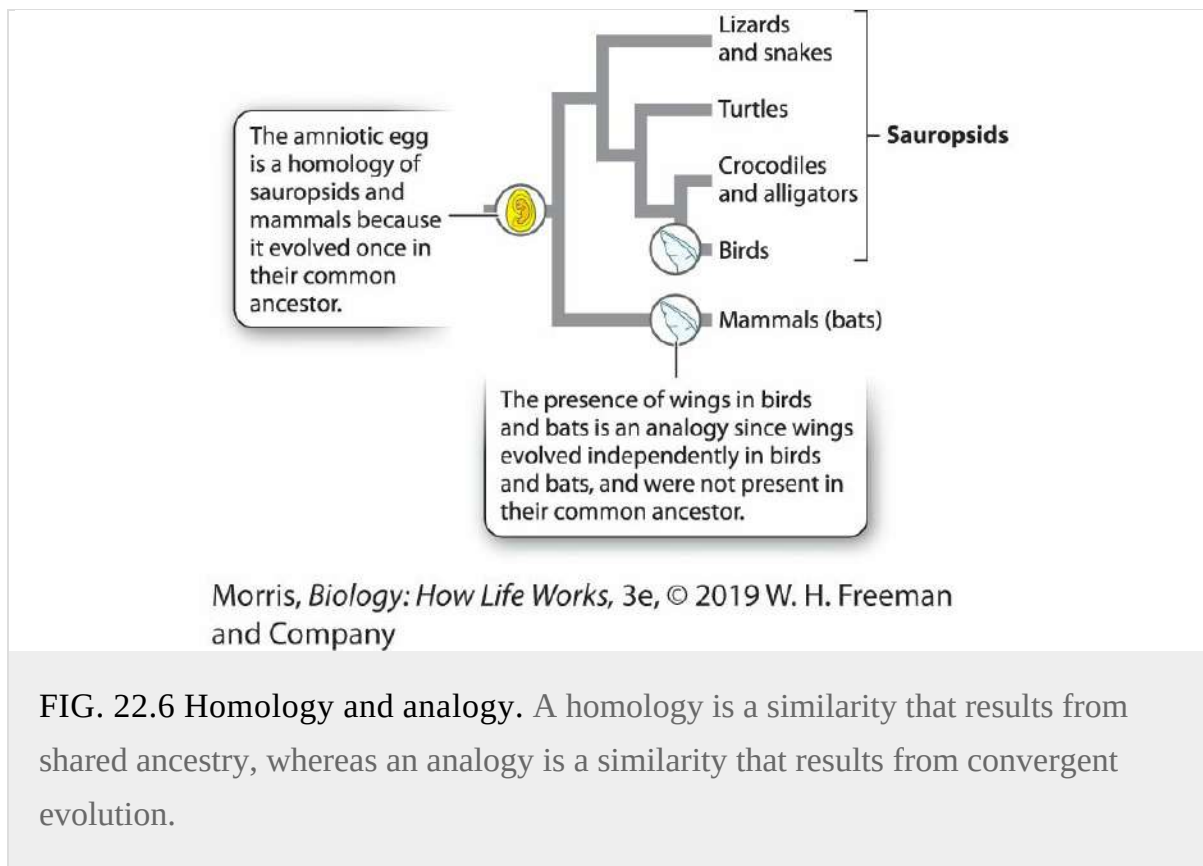

FIG. 22.6 Homology and analogy. A homology is a similarity that results from shared ancestry, whereas an analogy is a similarity that results from convergent evolution.

Not all similarities arise in this way, however. Think of wings, a character exhibited by both birds and bats. Much evidence supports the view that wings in these two groups do not reflect descent from a common, winged ancestor; instead, wings evolved independently in the two groups as adaptations to their environments. Similarities due to independent adaptation by different species are said to be **analogous**, or an **analogy** among different species. They are the result of convergent evolution.

Innumerable examples of convergent evolution less dramatic than wings are known. In some, we even understand the genetic basis of the convergence. For example, echolocation has evolved in both bats and dolphins, but not in most other mammals. Prestin is a protein in the hair cells of mammalian ears that is involved in hearing ultrasonic

frequencies: bats and dolphins independently evolved similar changes in their Prestin genes, apparently convergent adaptations for echolocation. Similarly, unrelated fish that live in freezing water at the poles, Arctic and Antarctic, have evolved similar glycoproteins that act as molecular “antifreeze,” preventing the formation of ice in their tissues.

In principle, two characters or character states are homologous if they are similar because of descent from a common ancestor that had the same character or character state; they are analogous if they arose independently because of similar selective pressures. In practice, to determine if characters observed in two organisms are homologous or analogous, we can weigh evidence that suggests where other traits place the two organisms on a phylogenetic tree, we can look at where on the organisms the trait occurs, and we can look at the anatomical or genetic details of how the trait is constructed. Wings in birds and bats are similar in morphological position (both are modified forelimbs), but differ in details of construction (the bat wing is supported by long fingers). Moreover, all other traits of birds and bats place them at the tips of different lineages, with many nonwinged species between them and their most recent common ancestor. Collectively, these pieces of information suggest that bats and birds did not retain wings from a common ancestor, but rather evolved wings independently.

**Shared derived characters enable biologists to reconstruct evolutionary history.**

Because homologies result from shared ancestry, only homologies, and not analogies, are useful in constructing phylogenetic trees. However, it turns out that only some homologies are useful. For example, character states that are unique to a given species or other monophyletic group can't tell us anything about its sister group. Because they evolved after the divergence of the group from its sister group, they can be used to characterize a group but not to relate it to other groups. Take wings again: we know that wings evolved in an ancestor of bats, but they do not occur in any other mammal. Because no other mammal has wings, this character cannot tell us which mammalian group is the sister group to bats. Similarly, homologies formed in the common ancestor of the entire group and therefore present in all its descendants do not help to identify sister-group relationships among the descendants of that common ancestor. All bats have wings, so wings by themselves do not help us to sort out evolutionary relationships among bat species.

What we need to build phylogenetic trees are homologies that are shared by some, but not all, of the members of the group under consideration. These shared derived characters are called **synapomorphies**. A derived character state is an evolutionary innovation, such as the change from five toes to a single toe—the hoof—in the ancestor of horses and donkeys. When this kind of novelty arises in the common ancestor of two taxa, it is shared by both; thus, the hoof is a synapomorphy defining horses and donkeys as sister groups.

**Fig. 22.7** illustrates the major synapomorphies that have helped us

construct the phylogeny of vertebrates. For example, the lung is a character present in lungfish and tetrapods, but absent in other vertebrates. The presence of lungs provides one piece of evidence that lungfish are the sister group of tetrapods. This approach to building a phylogenetic tree, or phylogenetic reconstruction, on the basis of synapomorphies is called **cladistics**.

FIG. 22.7 Synapomorphies, or shared derived characters. Homologies that are present in some, but not all, members of a group help us to construct phylogenetic trees.

## The simplest tree is often favored among multiple possible trees.

To see how synapomorphies help us chart out evolutionary relationships, let's consider the example in [Fig. 22.8](#). We begin with four species of animals (labeled “A” through “D”) for which we wish to build a phylogenetic tree. We will call this our ingroup, meaning it includes all of the groups for which we are interested in figuring out relationships. For comparison, we also include in our study a species that we believe is outside this ingroup—that is, it falls on a branch that splits off nearer the root of the tree—and so is called an outgroup (labeled “OG” in [Fig. 22.8](#)). Each species in the ingroup and the outgroup has a different combination of characters, such as leg number, presence or absence of wings, and whether development of young to adult is direct or goes through a pupal stage ([Fig. 22.8a](#)).

Since we are interested in the relationships among species A–D, we focus on potential synapomorphies, or character states shared by some, but not all, species within the group. For example, the table in [Fig. 22.8a](#) illustrating each group’s character states shows that only C and D have pupae. This character suggests that C and D have a common

ancestor that had pupae, and that the ancestor is not common to the other species. This would mean that C and D are more closely related to each other than either is to the other species. The alternatives to the explanation that C and D exclusively share a common ancestor are that C and D each evolved pupae independently or that pupae were present in the common ancestor of A–D but were lost in A and B.

How do we choose among the alternatives? Studies of the outgroup show that it does not form pupae, supporting the hypothesis that pupal development evolved within the ingroup. In practice, biologists examine multiple characters and choose the phylogenetic hypothesis that best fits all of the data.

How do we determine “best fit”? [Fig. 22.8b](#) illustrates three different hypotheses for the relationships among the species based on four characters and their various character states. Each reflects the sister-group relationship between C and D proposed earlier. The leftmost tree requires exactly four character-state changes during the evolution of these species: reduction of leg pairs to three in the group ABCD, wings in the group BCD, and pupae in group CD, plus a change of form of the mandible (jaw) in species D.

Now consider the middle tree in [Fig. 22.8b](#). It groups A and B together with a common ancestor not shared by the other species. A does not have wings but B, C, and D do. If A and B share a common ancestor exclusively, it means that wings must have evolved in the common ancestor of A,B, C, and D and then were lost only in A, or that the common ancestor of A and B lost wings and then wings arose

again in B—five changes in all.

The tree on the right groups A and B together, and requires two extra novel evolutionary changes for a total of six changes. No tree that we can construct from species A–D requires fewer than four evolutionary changes, so the left-hand version in [Fig. 22.8b](#) is the best available hypothesis of evolutionary relatedness. In fact, this is the phylogeny for a sample of species from the largest group of animals on Earth, the Hexapoda—insects and their closest relatives ([Fig. 22.8c](#)).

In general, trees with fewer character changes are preferred to ones that require more such changes because they provide the simplest explanation of the data. This approach is an example of **parsimony**, or choosing the simpler of two or more hypotheses to account for a given set of observations. When we use parsimony in phylogenetic reconstruction, we make the assumption that evolutionary change is typically rare. Over time, most features of organisms stay the same: we have the same number of ears as our ancestors, the same number of fingers, and so on. Thus, biologists commonly prefer the phylogenetic tree requiring the fewest evolutionary steps.

In systematics, parsimony suggests counting character changes on a phylogenetic tree to find the simplest tree for the data (the one with the fewest number of changes). Each change corresponds to a mutation (or mutations) in an ancestral species. Thus, the more changes or steps we propose, the more independent mutations we must also hypothesize.

Note also that it isn't necessary to make decisions in advance about which characters are homologies and which are analogies. We can

construct all possible trees and then choose the one requiring the fewest evolutionary changes. This is a simple matter for the example in [Fig. 22.8](#) because four species can be arranged into only 15 different trees. As the number of groups increases, however, the number of possible trees connecting them increases as well, and dramatically so. There are 105 possible trees for 5 groups, 945 trees for 6 groups, and nearly 2 million trees for 10 groups. For 50 groups, the possibilities balloon to  $3 \times 10^{76}$ ! Clearly, computers are required to sort through all the possibilities.

As is true for all hypotheses, phylogenetic hypotheses can be supported strongly or weakly. Biologists use statistical methods to evaluate a given phylogenetic hypothesis. Available character data may not strongly favor any hypothesis. When support for a specific branching pattern is weak, biologists commonly depict the relationships as unresolved and show multiple groups diverging from one node, rather than just two. Such branching patterns are not meant to suggest that multiple species diverged simultaneously, but rather to indicate that we lack the data to choose unequivocally among several different hypotheses of relationship. In [Part 2](#), we show unresolved branches in a number of groups. These shouldn't be read as admissions of defeat, but instead as problems awaiting resolution and opportunities for future research.

**Molecular data complement comparative morphology in reconstructing phylogenetic history.**

Trees can be built using anatomical features, but increasingly their construction relies on molecular data. The amino acids at particular positions in the primary structure of a protein can be used for this purpose, as can the nucleotides at specific positions along a strand of DNA.

From genealogy to phylogeny, tracing mutations in DNA or RNA sequences has revolutionized the reconstruction of historical genetic connections. Whether we are tracing the paternity of the children of Sally Hemings (mother of several of Thomas Jefferson's children), identifying the origin of a recent cholera epidemic in Haiti, or placing baleen whales near the hippopotamus family in a phylogenetic tree of mammals, molecular data are a rich source of phylogenetic insight.

There is nothing about molecular data that provides an intrinsically better record of history than does anatomical data; molecular data simply provide more details because there are more characters that can vary among the species. A sequence of DNA with hundreds or thousands of nucleotides can represent that many characters, as opposed to the tens of characters usually visible in morphological studies. For microbes and viruses, for example, very little morphology is available, so molecular information is critical for phylogenetic reconstruction. Once a gene or other stretch of DNA or RNA is identified that seems likely (based on previous studies of other species) to vary among the species to be studied, sequences are obtained and aligned to identify homologous nucleotide sites. Analyses of this kind commonly involve comparisons of sequences of about 1000 nucleotides from one or more genes. Increasingly, though, the

availability of whole-genome sequences is changing the way we do molecular phylogenetics. With this approach, rather than comparing the sequences of a few genes, we compare the sequences of entire genomes.

The process of using molecular data is conceptually similar to the process described earlier for morphological data. Through comparison to an outgroup, we can identify shared derived molecular characters (whether DNA nucleotides or amino acids in proteins) and generate the phylogeny on the basis of synapomorphies as before ([Fig. 22.9](#)).

FIG. 22.9 Phylogenetic reconstruction using molecular synapomorphies. We can use molecular synapomorphies to reconstruct phylogenies using sequence data.

Alternatively, we can reconstruct the phylogeny based on overall

similarity, rather than synapomorphies. With this approach, the assumption is that the descendants of a recent common ancestor will have had relatively little time to evolve differences, whereas the descendants of an ancient common ancestor have had a lot of time to do so. Thus, the extent of similarity (or distance) indicates how recently two groups shared a common ancestor. [Fig. 22.10](#) shows how distance methods work, using great apes as an example. We count the differences in DNA sequence for each pair of species. Those with the fewest differences are taken to be most closely related. In contrast, more distantly related species show a greater number of differences.

FIG. 22.10 Phylogenetic reconstruction using distance methods. Sequence data can be used to reconstruct phylogeny on the basis of distance, where distance is measured in number of sequence differences between species.

Underpinning this approach is the assumption that the rate of evolution is constant, or nearly so. If we find a total of six differences

between two species, for example, this approach assumes that three arose in each lineage since the common ancestor ([Fig. 22.11a](#)). However, if the rate of evolution varied from one lineage to the next, few changes may have occurred within one lineage and many in the other. As shown in [Fig. 22.11b](#), unequal rates of evolution in different lineages can result in inferring incorrect phylogenetic relationships. The rate-constancy assumption is less likely to be violated when we are using molecular data than when we are using morphological data. Recall from [Chapter 20](#) that the molecular clock is based on the observation of constant accumulation of genetic divergence through time.

FIG. 22.11 Evolutionary rates. (a) When rates of evolution are constant, a distance-based phylogenetic method works. (b) When rates of evolution are not constant, a distance-based phylogenetic approach can give an incorrect tree.

Molecular data are often combined with morphological data, and each can also serve as an independent assessment of the other. Not surprisingly, results from analyses of each kind of data are commonly compatible, at least for plants and animals rich in morphological characters.

The single largest library of taxonomic information is GenBank, the National Institutes of Health's genetic data storage facility. As of this writing, GenBank gives users access to more than 100 billion observations (mostly nucleotides) collected under more than 430,000 taxonomic names. A helpful Internet-based resource is the Encyclopedia of Life, which is gathering additional biological information about species, including ecology, geographic distributions, photographs, and sounds in pages for individual species that are easy to navigate. Another web resource, the Tree of Life, provides information on phylogenetic trees for many groups of organisms.

## Phylogenetic trees can help solve practical problems.

The sequence of changes on a tree from its root to its tips documents evolutionary changes that have accumulated through time. Trees suggest which groups are older than others, and which traits came first and which followed later. Proper phylogenetic placement, therefore,

reveals a great deal about evolutionary history. It can have practical consequences as well. For example, oomycetes, which are the microorganisms responsible for potato blight and other important diseases of food crops, were long thought to be fungi because they look like some fungal species. The discovery, using molecular characters, that oomycetes belong to a very different group of eukaryotic organisms has opened up new possibilities for understanding and controlling these plant pathogens. Similarly, in 2006, researchers used DNA sequences to identify the Malaysian parent population of a species of butterfly called lime swallowtails that had become an invasive species in the Dominican Republic, pinpointing the source populations from which natural enemies of this pest can be sought.

Phylogenetics was employed to solve a famous case in which a dentist in Florida was accused of infecting his patients with human immunodeficiency virus (HIV) ([Fig. 22.12](#)). HIV nucleotide sequences evolve so rapidly that biologists can build phylogenetic trees that trace the spread of specific strains from one individual to the next. Phylogenetic study of HIV present in samples from several infected patients, the HIV-positive dentist, and other individuals provided evidence that the dentist had, indeed, infected his patients.

HOW DO WE KNOW?

FIG. 22.12

Did an HIV-positive dentist spread the AIDS virus to his patients?

BACKGROUND

In the late 1980s, several patients of a Florida dentist contracted acquired immunodeficiency syndrome (AIDS), the disease caused by HIV infection. Molecular analysis showed that the dentist was HIV-positive.

#### HYPOTHESIS

It was hypothesized that the patients acquired HIV during dental procedures carried out by the infected dentist.

#### METHOD

Researchers obtained two HIV samples each (denoted 1 and 2 in the figure) from several people, including the dentist (Dentist 1 and Dentist 2), several of his patients (Patients A through G), and other HIV-positive individuals chosen at random from the local population (LP). In addition, a strain of HIV from Africa (HIVELI) was included in the analysis as an outgroup.

#### RESULTS

Biologists constructed a phylogeny based on the nucleotide sequence of a rapidly evolving gene in the genome of HIV. Because the gene evolves so quickly, its mutations preserve a record of evolutionary relatedness on a very fine scale. The HIV samples taken from some of the infected patients—patients A, B, C, E, and G—were more closely related to the dentist’s HIV than they were to samples taken from other infected individuals. Some patients’ sequences, however, were different enough from the dentist’s that they were not on the same part of the tree, suggesting that these patients, D and F, had acquired their HIV infections from other sources.

## CONCLUSION

HIV phylogeny makes it highly likely that the dentist infected several of his patients. The details of how the patients were infected remain unknown, but the safety practices now rigidly observed in dentistry make it unlikely that such a tragedy could occur again.

## FOLLOW-UP WORK

Phylogenies based on molecular sequence characters are now routinely used to study the origin and spread of infectious diseases, such as swine flu and Ebola.

SOURCE Hillis, D. M., J. P. Huelsenbeck, and C. W. Cunningham. 1994. "Application and Accuracy of Molecular Phylogenies." *Science* 264:671–677.

Similarly, phylogenetic studies of influenza virus strains show their

origins and subsequent movements among geographic regions and individual patients. Today, there is a growing effort to use specific DNA sequences as a kind of fingerprint or barcode for tracking biological material. Such information could quickly identify samples of shipments of meat as being from endangered species, or track newly emerging pests. The Consortium for the Barcode of Life has already accumulated species-specific DNA barcodes for more than 100,000 species. Phylogenetic evidence provides a powerful tool for evolutionary analysis and is useful across timescales ranging from months to the entire history of life, from the rise of epidemics to the origins of metabolic diversity.

#### Self-Assessment Questions

5. Despite having many traits in common with fish, including a streamlined body and fins, dolphins are mammals, not fish. Are these similar traits homologous or analogous?
6. Which type of homology is useful in building phylogenetic trees? Why is this kind of homology, and not others, useful?

## 22.3 THE FOSSIL RECORD

Phylogenies based on living organisms provide hypotheses about evolutionary history. Branching events toward the root of the tree occurred earlier than those near the tips, and characters change and accumulate along the path from the root to the tips. Fossils provide direct documentation of ancient life, and so, in combination, fossils and phylogenies provide strong complementary insights into evolutionary history.

### Fossils provide unique information.

Fossils can and do provide evidence for phylogenetic hypotheses. For example, they show that groups that branch from early nodes in phylogenies appear early in the geologic record. But the fossil record does more than this. First, fossils enable us to calibrate phylogenies in terms of time. It is one thing to infer that mammals diverged from the common ancestor of birds, crocodiles, turtles, and lizards and snakes before crocodiles and birds diverged from their common ancestor (see [Fig. 22.7](#)); it is another matter to state that birds and crocodiles diverged from each other about 240 million years ago, whereas the group represented today by mammals branched from other vertebrates about 80 million years earlier. As we saw in [Chapter 20](#), estimates of divergence time can be made using molecular sequence data, but all such estimates can be pinpointed to a specific time in history only by using fossils.

The evolutionary relationship between birds and crocodiles highlights a second kind of information provided by fossils. Not only

do fossils record past life, but they also provide our only record of extinct species. The phylogeny in [Fig. 22.7](#) contains a great deal of information, but it is silent about dinosaurs. Fossils demonstrate that dinosaurs once roamed Earth, and details of skeletal structure place birds among the dinosaurs in the vertebrate tree. Indeed, some remarkable fossils from China show that the dinosaurs most closely related to birds had feathers ([Fig. 22.13](#)).

Source: Getty Images/Getty Images.

FIG. 22.13 *Microraptor gui*, a remarkable fossil discovered in approximately 125-million-year-old rocks from China. The structure of its skeleton identifies *M. gui* as a dinosaur, yet it had feathers on its arms, tail, and legs.

A third, and also unique, contribution of fossils is that they place evolutionary events within the context of Earth's dynamic environmental history. Again, dinosaurs illustrate the point. As discussed in [Chapter 1](#), geologic evidence from several continents suggests that a large meteorite triggered drastic changes in the global environment 66 million years ago, leading to the extinction of dinosaurs (other than birds). In fact, at five times in the past, large environmental disturbances sharply decreased Earth's biological

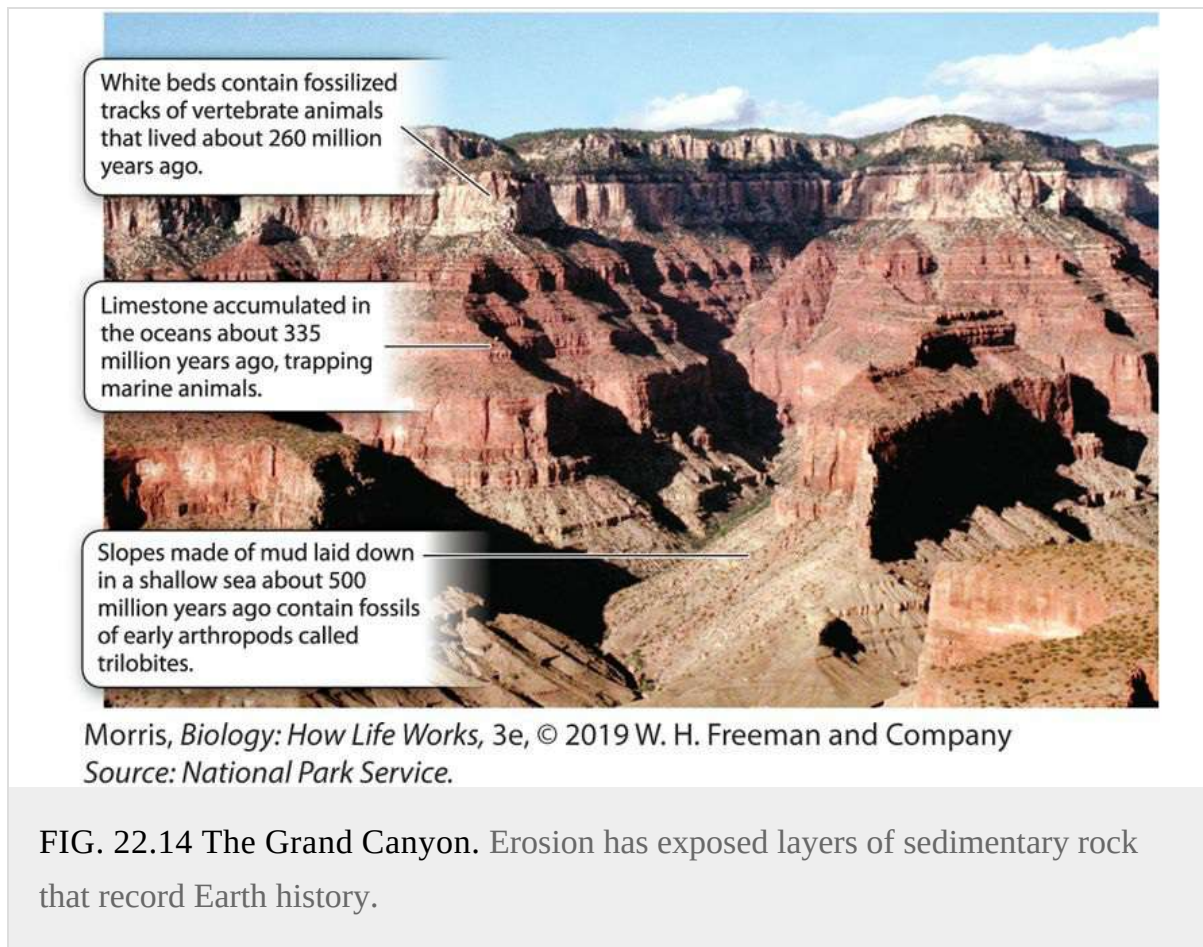

diversity. These events, called mass extinctions, have played a major role in shaping the course of evolution.

## Fossils provide a selective record of past life.

Fossils are the remains of once-living organisms, preserved through time in sedimentary rocks. If we wish to use fossils to complement phylogenies built from characters of modern organisms, we must understand how the processes of fossil formation govern what is and is not preserved.

For all its merits, the fossil record should not be thought of as a complete encyclopedia of everything that ever walked, crawled, or swam across our planet's surface. Fossilization requires burial, as when a clam dies on the seafloor and is quickly covered by sand, or when a leaf falls to the forest floor and ensuing floods cover it in mud.

Through time, accumulating sediments from sand or mud or soil harden into sedimentary rocks, such as those exposed so dramatically in the walls of the Grand Canyon ([Fig. 22.14](#)). If they are not buried, the remains of organisms are eventually recycled by biological and physical processes, and no fossil forms. In general, the fossil record of marine life is more completely sampled than that for land-dwelling creatures because marine habitats are more likely than those on land to be places where sediments accumulate and become rock. Thus, trees and elks living high in the Rocky Mountains have a low probability of fossilization, whereas clams and corals on the shallow seafloor are commonly buried and become fossils.

Biological factors also contribute to the incompleteness of the fossil record. Most fossils preserve just the hard parts of organisms, those features that resist decay after death. For animals, this usually means mineralized skeletons. Clams and snails that secrete shells of calcium carbonate have excellent fossil records. More than 80% of the clam species found today along California's coast also occur as fossils in sediments deposited during the past million years. In contrast, nematodes, tiny worms that may be the most abundant animals on Earth, have no mineralized skeletons and are represented almost nowhere in the fossil record. The wood and pollen of plants, which are made in part of decay-resistant organic compounds, enter the fossil record far more commonly than do flowers. And, among unicellular organisms, the skeleton-forming diatoms, radiolarians, and

foraminiferans have exceptionally good fossil records, whereas most amoebas are unrepresented.

Together, then, the properties of organisms (do they make skeletons or other features that resist decay after death?) and environment (did the organisms live in a place where burial was likely?) determine the probability that an ancient species will be represented in the fossil record.

Organisms that lack hard parts can leave a fossil record in two other distinctive ways. Many animals leave tracks and trails as they move about or burrow into sediments. These fossils of trails, rather than body parts, called **trace fossils**, range from dinosaur tracks to the feeding trails of snails and trilobites. In essence, they preserve a record of both anatomy and behavior (**Fig. 22.15**).

Source: José Antonio Hernaiz/AGE Fotostock.

FIG. 22.15 Trace fossils. These footprints in 150-million-year-old rocks record both the structure and the behavior of the dinosaurs that made them.

Organisms can also contribute [molecular fossils](#) to the rocks. Most biomolecules decay quickly after death. Proteins and DNA, for example, generally break down before they can be preserved, although, remarkably, the Neanderthal genome has been pieced together from DNA in 40,000-year-old bones ([Chapter 23](#)). Other molecules, especially lipids like cholesterol, are more resistant to decomposition. Sterols, bacterial lipids, and some pigment molecules can accumulate in sedimentary rocks, documenting organisms that rarely form conventional fossils, especially bacteria and single-celled eukaryotes.

Rarely, unusual conditions preserve fossils of unexpected quality, including animals without shells, delicate flowers or mushrooms, fragile seaweeds or bacteria, and even the embryos of plants and animals. For example, 505 million years ago, during the Cambrian Period, a sedimentary rock formation called the Burgess Shale accumulated on a relatively deep seafloor covering what is now British Columbia. Waters just above the basin floor contained little or no oxygen. Thus, when mud swept into the basin, entombed animals were sealed off from scavengers, disruptive burrowing activity, and even bacterial decay. For this reason, Burgess rocks preserve a remarkable sampling of marine life during the initial diversification of animals ([Fig. 22.16](#)).

FIG. 22.16 A Burgess Shale fossil. This fossil is *Opabinia regalis*, an extinct early relative of the arthropods, from the 505-million-year-old Burgess Shale.

The Messel Shale formed more recently—about 50 million years

ago—in a lake in what is now Germany. Release of toxic gases from deep within the Messel lake suffocated local animals, and their carcasses settled into muds on the lake floor that were oxygen-poor and sealed off from microbes that help decompose other organisms. In the Messel record, fish, birds, mammals, and reptiles are preserved as complete and articulated skeletons, and mammals retain impressions of fur and color patterning ([Fig. 22.17](#)). Plants were also beautifully preserved, as were insects, some with a striking iridescence still intact. Messel rocks provide a truly outstanding snapshot of life on land as the age of mammals began.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 22.17 A Messel Shale fossil. Even the furry tail of this extinct squirrel-like mammal is preserved in this remarkable 50-million-year-old fossil.

In general, the fossil record preserves some aspects of biological history well and others poorly. Fossils provide a good sense of how the forms, functions, and diversity of skeletonized animals have changed over the past 500 million years. The same is true for land plants and

unicellular organisms that form mineralized skeletons. Collectively, these fossils shed light on major patterns of morphological evolution and diversity change through time; their geographic distributions record the movements of continents over millions of years; and the radiations and extinctions they document show how life responds to environmental change, both gradual and catastrophic.

## Geologic data indicate the age and environmental setting of fossils.

How do we know the age of a fossil? Beginning in the nineteenth century, geologists recognized that the types of fossils found in layers of rock change systematically from the bottom of a sedimentary rock formation to its top. As more of Earth's surface was mapped and studied, it became clear that certain fossils always occur in layers that lie beneath (and so are older than) layers that contain other species. From these patterns, geologists concluded that fossils mark time in Earth history. At first, geologists could not explain why fossils changed from one bed to the next, but after Darwin the reason became apparent: fossils record the evolution of life on Earth. Geologists eventually used these data to map out the [geologic timescale](#), the series of time divisions that mark Earth's long history ([Fig. 22.18](#)).

FIG. 22.18 The geologic timescale, showing major events in the history of life on Earth.

The layers of fossils in sedimentary rocks can tell us that some rocks are older than others, but they cannot by themselves provide an absolute age. Calibration of the timescale became possible with the discovery of radioactive decay. In [Chapter 2](#), we discussed isotopes, variants of an element that differ from one another in terms of the number of neutrons they contain. Many isotopes are unstable and spontaneously break down, ejecting neutrons, electrons, or other

particles to form other, more stable isotopes. In the laboratory, scientists can measure how fast unstable isotopes decay. Then, by measuring the amounts of the unstable isotope and its stable daughter isotope inside a mineral, they can determine when the mineral formed.

Archaeologists commonly use the radioactive decay of the isotope carbon-14, or  $^{14}\text{C}$ , to date wood and bone, a process called **radiometric dating**.  $^{14}\text{C}$  is an isotope of carbon with eight neutrons and six protons instead of the more stable (and more common) configuration of six neutrons and six protons. As shown in **Fig. 22.19**, cosmic rays continually generate neutrons that collide with nitrogen in the atmosphere to form  $^{14}\text{C}$ , much of which is incorporated into atmospheric carbon dioxide ( $\text{CO}_2$ ). Through photosynthesis, carbon dioxide that contains  $^{14}\text{C}$  is incorporated into wood, and animals incorporate small amounts of  $^{14}\text{C}$  into their tissues when they eat plant material. The unstable  $^{14}\text{C}$  in these tissues begins to break down immediately, losing an electron to form  $^{14}\text{N}$ , a stable isotope of nitrogen. Once the organism dies,  $^{14}\text{C}$  is no longer added, so the clock of radioactive carbon starts to tick. Laboratory measurements indicate that half of the  $^{14}\text{C}$  in a given sample will decay to nitrogen in 5730 years, a period called its **half-life** (**Fig. 22.19**). All isotopes of elements have a unique half-life, which vary in length depending on their stability. Armed with this information, scientists can measure the amount of  $^{14}\text{C}$  in an archaeological sample and, by comparing it to the amount of  $^{14}\text{C}$  in a sample of known age (based on annual rings in trees, for example, or yearly growth of coral skeletons), determine the age of the sample.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 22.19  $^{14}\text{C}$  decay. Scientists can determine the age of relatively young materials such as wood and bone from the amount of  $^{14}\text{C}$  they contain.

Because its half-life is so short (by geologic standards),  $^{14}\text{C}$  is useful only in dating materials younger than 50,000 to 60,000 years. Beyond that point, too little  $^{14}\text{C}$  is left in materials to measure accurately. Older geologic materials are commonly dated using the radioactive decay of uranium (U) to lead (Pb):  $^{238}\text{U}$ , which may be incorporated in trace amounts into the minerals of volcanic rocks, breaks down to  $^{206}\text{Pb}$  with a half-life of 4.47 billion years;  $^{235}\text{U}$  decays to  $^{207}\text{Pb}$  with a half-life of 704 million years. Calibration of the geologic timescale is based mostly on the ages of volcanic ash found in sedimentary rocks that contain key fossils, as well as volcanic rocks that intrude into (and so are younger than) layers of rock containing fossils. In turn, the ages of those fossils provide calibration points for phylogenies.

The sedimentary rocks that contain fossils also preserve, encrypted in their physical features and chemical composition, information about the environment in which they formed. Sandstone beds, for example, may have rippled surfaces, like the ripples produced by currents that we see today in the sand of a seashore or lake margin. Pyrite ( $\text{FeS}_2$ ), or fool's gold, forms when  $\text{H}_2\text{S}$  generated by anaerobic bacteria reacts with iron. Because these conditions generally occur where oxygen is absent, the presence of pyrite in ancient sedimentary rocks can indicate that the environment was depleted of oxygen at the time that the rock formed.

We might think our moment in geologic time is representative of

Earth as it has always existed, but nothing could be further from the truth. In terms of the location and sizes of its continents, ocean chemistry, and atmospheric composition, the Earth we experience today is unlike any previous state of the planet. Today, for example, the continents are distributed widely over the planet's surface, but 280 million years ago they were clustered in a supercontinent called Pangaea ([Fig. 22.20](#)).

Source: Pangaea from © Global Paleogeography and Tectonics © 2016 Colorado Plateau Geosystems Inc.

FIG. 22.20 Pangaea, 280 million years ago. Plate tectonics has shaped and reshaped Earth's geography through time. The white areas near the South Pole are glacial ice.

Oxygen gas permeates most surface environments of Earth today, but 3 billion years ago, there was no O<sub>2</sub> anywhere. And, just 20,000 years ago, 2 km of glacial ice stood where Boston lies today. Sedimentary rocks record the changing state of Earth's surface over billions of years and show that life and environment have changed together through time, each influencing the other.

## Fossils can contain unique combinations of characters.

Phylogenies hypothesize impressive morphological and physiological shifts through time—amphibians from fish, for example, or land plants from green algae. Do fossils capture a record of these transitions as they took place?

Let's begin with an example introduced earlier in this chapter. Phylogenies based on living organisms generally place birds as the sister group to crocodiles and alligators, but birds and crocodiles are decidedly different from each other in structure. For example, birds have wings, feathers, toothless bills, and a number of other skeletal features distinct from those of crocodiles. In 1861, just two years after publication of *On the Origin of Species*, German quarry workers discovered a remarkable fossil that remains paleontology's most famous example of a form that is transitional between two groups. *Archaeopteryx lithographica*, now known from 11 specimens splayed for all time in fine-grained limestone, lived 150 million years ago. Its skeleton shares many characters with dromaeosaurs, a group of small, agile dinosaurs, but several features—its pelvis, its braincase, and, especially, its winglike forearms—are distinctly birdlike. Spectacularly, the fossils preserve evidence of feathers. *Archaeopteryx* clearly suggests a close relationship between birds and dinosaurs, and phylogenetic reconstructions that include information from fossils show that many of the characters found today in birds accumulated through time in their dinosaur ancestors. As noted earlier, even feathers first evolved in dinosaurs ([Fig. 22.21](#)).

FIG. 22.21 Dinosaurs and birds. A number of dinosaur fossils link birds phylogenetically to their closest living relatives, the crocodiles. *Data from C. Zimmer, 2009, The Tangled Bank, Greenwood Village, CO: Roberts and Company.*

*Tiktaalik roseae* and other skeletons in rocks deposited 375 to 362 million years ago record an earlier but equally fundamental transition: the colonization of land by vertebrates. Phylogenies built from

characters of modern animals show that all land vertebrates, from amphibians to mammals, are descended from a common ancestral fish. As seen in [Fig. 22.22](#), *Tiktaalik* had fins, gills, and scales like other fish of its day, but its skull was flattened, more like that of a crocodile than a fish, and it had a functional neck and ribs that could support its body—features today found only in tetrapods. Along with other fossils, *Tiktaalik* captures key moments in the evolutionary transition from water to land, confirming the predictions of phylogeny.

#### HOW DO WE KNOW?

### FIG. 22.22

## Do fossils bridge the evolutionary gap between fish and tetrapod vertebrates?

#### BACKGROUND

Phylogenies based on both morphological and molecular characters of modern animals indicate that fish are the closest relatives of four-legged land vertebrates.

#### HYPOTHESIS

Land vertebrates evolved from fish by modifications of the skeleton and internal organs that made it possible for them to live on land.

#### OBSERVATION

Fossil skeletons 390 to 360 million years old show a mix of features seen in living fishes and amphibians. Older fossils have fins, fishlike heads, and gills, whereas younger fossils have weight-bearing legs, skulls with jaws able to grab prey, and ribs that help ventilate lungs. Paleontologists predicted that key intermediate fossils would be preserved in 380–370-million-year-old rocks.

In 2004, Edward Daeschler, Neil Shubin, and Farish Jenkins discovered the remarkable fossil *Tiktaalik* in rocks laid down by a meandering stream of just the right age. *Tiktaalik* had fins, scales, and gills like fishes, but an amphibian-like skull and a true neck (which fishes lack). Its limbs preserve wrist bones and fingers broadly similar to those in tetrapod vertebrates. Even so, as the reconstruction shows, its forelimbs were not completely adapted for movement on land.

### CONCLUSION

Fossils confirm the phylogenetic prediction that tetrapod vertebrates evolved from fish by the developmental modification of limbs, skulls, and other features.

### FOLLOW-UP WORK

Research into the genetics of vertebrate development shows that the limbs of fish and amphibians are shaped by similar patterns of gene expression, providing further support for the phylogenetic connection between the two

groups.

SOURCE Daeschler, E. B., N. H. Shubin, and F. A. Jenkins, Jr. 2006. "A Devonian Tetrapod-like Fish and the Evolution of the Tetrapod Body Plan." *Nature* 440:757–763.

## Rare mass extinctions have altered the course of evolution.

Beginning in the 1970s, American paleontologist Jack Sepkoski scoured the paleontological literature, recording the first and last appearances in the geologic record for every genus of marine animals he could find. The results of this monumental effort are shown in [Fig. 22.23](#). Sepkoski's diagram shows that animal diversity has increased over the past 540 million years: the biological diversity of animals in today's oceans may well be higher than it has ever been in the past. At the same time, it is clear that animal evolution is not simply a history of continual accumulation.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 22.23 Mass extinctions. Because they eliminate much of the life found on Earth at the time, mass extinctions allow new groups to proliferate and diversify. Source: Sepkoski's Online Genus Database. <http://strata.geology.wisc.edu/jack/>.

Repeatedly during the past 500 million years, animal diversity in the oceans has dropped both rapidly and substantially; waves of extinctions have also occurred on land. Known as **mass extinctions**, these events eliminated ecologically important taxa, thereby providing evolutionary opportunities for the survivors. In [Chapter 21](#), we explored how species often radiate on islands where there is little or no competition or predation. For survivors, mass extinctions provided ecological opportunities on a grand scale.

The best-known mass extinction occurred 66 million years ago, at the end of the Cretaceous Period (rightmost drop in [Fig. 22.23](#)). On land, dinosaurs disappeared abruptly, following more than 150 million

years of dominance in terrestrial ecosystems. In the oceans, cephalopod mollusks called ammonites, which had long been abundant predators, became extinct, and most skeleton-forming microorganisms in the oceans disappeared as well. As discussed in [Chapter 1](#), a large body of geologic evidence supports the hypothesis that this biological catastrophe was caused by the impact of a giant meteorite. By eliminating dinosaurs and much more of the biological diversity that had built up over millions of years on land, the mass extinction at the end of the Cretaceous Period had the closely related effect of generating new evolutionary possibilities for those terrestrial animals that survived the event, including mammals.

Before dinosaurs ever walked on Earth, the greatest of all mass extinctions occurred 252 million years ago, at the end of the Permian Period, when environmental catastrophe eliminated half of all families in the oceans and approximately 80% of all genera. Estimates of marine species losses run as high as 90%. Geologists have hypothesized that this mass extinction resulted from the catastrophic effects of massive volcanic eruptions. At the end of the Permian Period, most continents were gathered into the supercontinent Pangaea (see [Fig. 22.20](#)), and a huge ocean covered more than half of the Earth. Levels of oxygen in the deep waters of this ocean were low, as the result of sluggish circulation and warm seawater temperatures. Then, a massive outpouring of ash and lava—a million times larger than any volcanic eruption experienced by humans—erupted across what is now Siberia. Enormous emissions of carbon dioxide and methane from the volcanoes caused global warming (so even less oxygen reached deep oceans) and ocean acidification (making it difficult for animals and

algae to secrete calcium carbonate skeletons).

The three-way insult of lack of oxygen, ocean acidification, and global warming doomed many species on land and in the seas. Seascapes dominated for 200 million years by corals and shelled invertebrates called brachiopods disappeared. As ecosystems recovered from this mass extinction, they came to be dominated by new groups descended from survivors of the extinction. Bivalve and gastropod mollusks diversified in the absence of their former competitors; new groups of arthropods radiated, including the ancestors of the crabs and shrimps we see today; and surviving sea anemones evolved a new capacity to make skeletons of calcium carbonate, resulting in the corals that build modern reefs. In short, mass extinction reset the course of evolution, much as it did at the end of the Cretaceous Period.

When you stroll through a zoo or snorkel above a coral reef, you are not simply seeing the products of natural selection played out over Earth history: you are encountering the descendants of Earth's biological survivors. Current biological diversity reflects the interplay through time of natural selection and rare massive perturbations to ecosystems on land and in the sea. The fossil record provides a silent witness to our planet's long and complex evolutionary history.

#### Self-Assessment Questions

7. You have just found a novel vertebrate skeleton in 200-million-year-old rocks. How would you integrate this new fossil species into the phylogenetic tree depicted in [Fig. 22.7](#)?

8. Which of the following is most likely to have a good fossil record: earthworms, birds, corals, or tunicates (sea squirts)?
9. How can the fossil record be used to determine both the relative timescale and the absolute timescales of past events?
10. What is the significance of *Archaeopteryx* and *Tiktaalik*?
11. How have mass extinctions shaped the ecological landscape?

## 22.4 COMPARING EVOLUTION'S TWO GREAT PATTERNS

The diversity of life we see today is the result of evolutionary processes playing out over geologic time. Processes of evolution can be studied by experiment, both in the field and in the laboratory ([Chapter 1](#)), but experimentally exploring evolutionary history is another matter. There is no experiment we can do to determine why the dinosaurs became extinct—we cannot rerun the events of 66 million years ago, this time without the meteorite impact. Instead, the history of life must be reconstructed from evolution's two great patterns: the nested similarity observed in the forms and molecular sequences of living organisms, and the direct historical archive of the fossil record.

### Phylogeny and fossils complement each other.

The great advantage of reconstructing evolutionary history from living organisms is that we can use a full range of features—skeletal morphology, cell structure, DNA sequence—to generate phylogenetic hypotheses. The disadvantage of using this kind of comparative biology is that we lack evidence of extinct species, any direct connection of phylogeny to time, and the environmental context of the species being studied. This is where the fossil record comes into play. Fossil evidence, in turn, has strengths and limitations that complement the evolutionary information in living organisms.

For example, we can use phylogenetic methods based on DNA sequences to infer that birds and crocodiles are closely related, but only fossils can show that the evolutionary link between birds and crocodiles runs through dinosaurs. Likewise, only the fossil record can show that mass extinction removed the dinosaurs, paving the way for the emergence of modern mammals. Paleontologists and biologists work together to understand evolutionary history. Biology provides a functional and phylogenetic framework for the interpretation of fossils, and fossils provide a record of life's history in the context of continually changing environments.

## Agreement between phylogenies and the fossil record provides strong evidence of evolution.

Phylogenies based on morphological or molecular comparisons of living organisms make hypotheses about the timing of evolutionary changes through Earth history. We humans are a case in point. As we discuss in [Chapter 23](#), comparisons of DNA sequences suggest that chimpanzees are our closest living relatives. This hypothesis is supported by observations that chimpanzees and humans share many features visible at a glance. However, among other differences, chimpanzees have smaller stature, smaller brains, long arms that facilitate knuckle-walking (the arms help support the body as the chimpanzee moves forward), a more prominent snout, and larger teeth.

How did these differences accumulate over the 7 million years or so since the human and chimpanzee lineages diverged? Fossils

painstakingly unearthed over the past century show, for example, that the ability to walk upright evolved before humans evolved a larger-than-average brain. Lucy, a famous specimen of *Australopithecus afarensis* dating to approximately 3.2 million years ago, was fully bipedal but had a brain the size of a chimpanzee's. Fossils like Lucy that are a mix of ancestral (brain size) and derived (bipedalism) characters provide strong support for our phylogenetic tree that shows humans and chimpanzees as sister taxa.

The agreement of comparative biology and the fossil record can be seen at all scales of phylogeny. Humans form one tip of a larger branch that contains all members of the primate family. Primates, in turn, are nested within a larger branch occupied by mammals, and mammals are nested within a still larger branch containing all vertebrate animals, which include fish. This arrangement predicts that the earliest fossil fishes should be older than the earliest fossil mammals, the earliest fossil mammals older than the earliest primates, and the earliest primates older than the earliest humans. This is precisely what the fossil record shows ([Fig. 22.24](#)).

FIG. 22.24 Phylogeny and fossils of vertebrates. The branching order of the phylogeny corresponds to the order of appearance of each group in the fossil record.

The agreement between fossils and phylogenies can be seen again and again when we examine different branches of the tree of life or, for that matter, the tree as a whole. All phylogenies indicate that microorganisms diverged early in evolutionary history, whereas mammals, flowering plants, and other large complex organisms diverged more recently. The tree's shape implies that diversity has accumulated through time, beginning with simple organisms and later adding complex macroscopic forms.

The geologic record shows the same pattern. The vastness of the timescale may be daunting, but the message is simple: fossils show that life was, indeed, microbial for its first 3 billion years. Only at about

580 million years ago did the first animals arise, kicking off the long evolutionary journey that eventually resulted in our own species (see [Fig. 22.18](#); [Chapter 23](#)).

In [Part 2](#) of this book, we explore the evolutionary history of life in some detail. Here, it is sufficient to draw a key general conclusion: the fact that comparative biology and fossils, two complementary but independent approaches to reconstructing the evolutionary past, yield the same history is powerful evidence of evolution.

Self-Assessment Question

12. A popular creationist criticism of evolution is that the theory of evolution is impossible to falsify (that is, to prove wrong). Using information on phylogeny and the fossil record, imagine a discovery that would indeed falsify the theory.

## CORE CONCEPTS SUMMARY

**22.1 READING A PHYLOGENETIC TREE:** A phylogenetic tree is a hypothesis of the evolutionary relationships among organisms.

The nested pattern of similarities seen among organisms is a result of descent with modification and can be represented as a phylogenetic tree. [page 468](#)

All organisms living today, regardless of their placement on a phylogenetic tree, have evolved for the same amount of time from the most recent common ancestor of all organisms, so none is more or less “evolved” than the others. [page 469](#)

Sister groups are more closely related to one another than they are to any other group. [page 469](#)

A node is a branching point on a phylogenetic tree, and it can be rotated without changing the interpretation of evolutionary relationships. [page 469](#)

Evolutionary relatedness is determined by following the sequence of nodes on a phylogenetic tree over time, rather than by assessing the order of the tips across a page. [page 470](#)

A monophyletic group includes all the descendants of a common ancestor. [page 470](#)

A paraphyletic group includes some, but not all, of the descendants of a common ancestor. [page 470](#)

A polyphyletic group includes organisms from distinct groups

based on shared, convergent characters, and does not include a common ancestor. [page 470](#)

Organisms are classified into domain, kingdom, phylum, class, order, family, genus, and species. [page 471](#)

**22.2 BUILDING A PHYLOGENETIC TREE:** A phylogenetic tree is built on the basis of shared derived characters.

Characters, or traits, existing in different states are used to build phylogenetic trees. [page 472](#)

Homologies are similarities based on shared ancestry, while analogies are similarities based on independent convergently evolved adaptations. [page 472](#)

Homologies can be ancestral, unique to a particular group, or present in some, but not all, of the descendants of a common ancestor (shared derived characters). [page 472](#)

Only shared derived characters, or synapomorphies, are useful in constructing a phylogenetic tree. [page 473](#)

Molecular data, such as DNA sequences, provide a wealth of characters that complement other types of information in building phylogenetic trees. [page 475](#)

Phylogenetic trees can be used to understand evolutionary relationships of organisms and solve practical problems, such as how viruses evolve over time. [page 478](#)

**22.3 THE FOSSIL RECORD:** The fossil record provides direct

evidence of evolutionary history.

Fossils are the remains of organisms preserved in sedimentary rocks. [page 479](#)

The fossil record is imperfect because fossilization requires burial in sediment, sediments accumulate episodically and discontinuously, and fossils typically preserve only the hard parts of organisms. [page 479](#)

Radioactive decay of unstable isotopes of elements provides a means of dating rocks. [page 483](#)

Transitional fossils, such as *Archaeopteryx* and *Tiktaalik*, help us understand important steps in evolution, including the bird–dinosaur transition and the fish–tetrapod transition, respectively. [page 484](#)

The history of life on Earth is characterized by five mass extinctions that changed the course of evolution by eliminating some groups and providing opportunities for other groups to diversify. [page 486](#)

Mass extinction at the end of the Cretaceous Period 66 million years ago included the extinction of the dinosaurs (other than birds). [page 486](#)

The extinction at the end of the Permian Period 252 million years ago is the largest documented mass extinction in the history of Earth. [page 487](#)

## **22.4 COMPARING EVOLUTION’S TWO GREAT PATTERNS:**

Phylogeny and fossils provide independent and corroborating evidence of evolution.

Phylogeny makes use of living organisms, while the fossil record supplies a record of species that no longer exist, absolute dates, and environmental context. [page 487](#)

Data from phylogeny and fossils are often in agreement, providing strong evidence for evolution. [page 488](#)

## CHAPTER 23 Human Origins and Evolution

DLILLC/Corbis/VCG/Getty Images

---

### CORE CONCEPTS

**23.1 THE GREAT APES:** Anatomical, molecular, and fossil evidence shows that the human lineage branches off the great apes tree.

**23.2 AFRICAN ORIGINS:** According to phylogenetic analysis of mitochondrial and the Y chromosome DNA sequences, our species arose in Africa.

**23.3 HUMAN TRAITS:** The human lineage acquired a number of distinctive features in the 5–7 million years since the most recent common ancestor of humans and chimpanzees.

**23.4 HUMAN GENETIC VARIATION:** Human history has had an important impact on patterns of genetic variation in our species.

**23.5 CULTURE, LANGUAGE, AND CONSCIOUSNESS:** Culture, language, and consciousness are developed to a remarkable degree in humans.

---

Charles Darwin carefully avoided discussing the evolution of our own species in *On the Origin of Species*. He wrote only that he saw “open fields for far more important researches,” and that “light will be thrown on the origin of man and his history.” Darwin, an instinctively cautious man, realized that the ideas presented in *The Origin* were controversial enough without adding a discussion of humans into the mix. He presented his ideas on human evolution to the public only when he published *The Descent of Man* 12 years later, in 1871.

As it turned out, Darwin’s delicate sidestepping of human origins had little effect. The initial print run of *The Origin* sold out on the day of publication, and the public was perfectly capable of reading between the lines. The Victorians found themselves wrestling with the book’s

revolutionary message: that humans are a species of ape.

Darwin's conclusions remain controversial to this day among some members of the general public, but they are not controversial among scientists. The evidence that humans are descended from a line of apes whose modern-day representatives include gorillas and chimpanzees is compelling. We know now that approximately 5–7 million years ago the family tree of the great apes split, with one branch ultimately giving rise to chimpanzees and the other to our species. Those 5–7 million years hold the key to our humanity. It was over this period—a brief span by evolutionary standards—that the attributes that make our species so remarkable arose. This chapter discusses what happened over those 5–7 million years and how humans came to be the way we are.

## 23.1 THE GREAT APES

We can approach the question of humans' place in the tree of life in three different ways: through comparative anatomy, through molecular analysis, and through the fossil record. In this section, we refer to data from all three sources as we apply the standard methods of phylogenetic reconstruction ([Chapter 22](#)) to figure out the evolutionary relationships between humans and other mammals.

### Comparative anatomy shows that the human lineage branches off the great apes tree.

The approximately 400 species of [primates](#) include prosimians (lemurs, bushbabies), monkeys, and apes ([Fig. 23.1](#)). All primates share a number of general anatomical features that distinguish primates from other mammals: nails rather than claws, together with a versatile thumb, allow objects to be manipulated more dexterously, and eyes on the front of the face instead of the side allow stereoscopic (three--dimensional) vision.

FIG. 23.1 The primate family tree. This tree shows the evolutionary relationships of prosimians, monkeys, and apes.

Prosimians are thought to represent a separate primate group from the one that gave rise to humans. Lemurs, which today are found only on the island of Madagascar, are therefore only distantly related to humans. Monkeys underwent independent bouts of evolutionary change in the Americas and in Africa and Eurasia, so their family tree is split along geographic lines into New World and Old World monkeys. Although both New World and Old World groups have evolved similar habits, there are basic distinctions. Notably, the teeth of the two groups differ. Also, in New World monkeys the nostrils tend to be widely spaced, whereas in Old World species they are closer together.

One line of Old World monkeys gave rise to the apes, which lack a tail and show more complex behaviors than other monkeys. The apes are split into two groups, the lesser apes and the great apes ([Fig. 23.2](#)). Lesser apes include the 14 species of gibbon, all of which are found in Southeast Asia. The great apes include orangutans (Southeast Asia), gorillas (Africa), chimpanzees (Africa), and humans. Taxonomists classify all the descendants of a specified common ancestor as belonging to a monophyletic group ([Chapter 22](#)). Thus, humans, blue whales, and hedgehogs are all mammals because all three are descended from the first mammal, the original common ancestor of all mammals. Because human ancestry can be traced to the common ancestor of orangutans, gorillas, and chimpanzees, humans, too, are members of the monophyletic great apes group.

FIG. 23.2 The family tree of the lesser and great apes. The apes consist of two major groups, the lesser apes and the great apes. The great apes group includes humans.

Molecular analysis reveals that the human lineage split from the chimpanzee lineage about 5–7 million years ago.

Which great ape is most closely related to humans? That is, which is the sister group of humans? Traditional approaches of reconstructing evolutionary history by comparing anatomical features failed to determine which of two candidates, gorillas or chimpanzees, is the sister group to humans. It was only with the introduction of molecular methods of assessing evolutionary relationships—through the comparison of DNA and amino acid sequences from the different

species—that the answer was determined. The closest relative to humans is the chimpanzee ([Fig. 23.2](#)), or, more accurately, the chimpanzees, plural, because there are two closely related chimpanzee species, the smaller of which is often called the bonobo.

Just how closely are humans and chimpanzees related? To answer this question, we need to know the timing of the evolutionary split that led to chimpanzees along one fork and to humans along the other. As discussed in [Chapter 20](#), DNA sequence differences accumulate between isolated populations or species, and they do so at a more or less constant rate. As a result, the extent of sequence difference between two species is a good indication of the amount of time they have been separate, meaning the amount of time since their last common ancestor.

Mary-Claire King and Allan Wilson at the University of California at Berkeley carried out the first thorough comparison of DNA molecules between humans and chimpanzees before the advent of DNA sequencing methods ([Fig. 23.3](#)).

#### HOW DO WE KNOW?

### FIG. 23.3

## How closely related are humans and chimpanzees?

#### BACKGROUND

Phylogenetic analysis based on anatomical characteristics had established that chimpanzees are closely related to humans. In 1975, Mary-Claire King and Allan Wilson used molecular techniques to determine *how*

closely related the two species are.

### HYPOTHESIS

Despite the marked anatomical and behavioral differences between chimpanzees and humans, the genetic distance between the two species is small, implying a relatively recent common ancestor.

### METHOD

When two complementary strands of DNA are heated, the hydrogen bonds between the two DNA strands break at approximately 95°C and the double helix denatures, or separates ([Chapter 12](#)). Complementary strands that have some mismatches separate at a temperature slightly lower than 95°C because fewer hydrogen bonds are holding the helix together. More mismatches between the two sequences results in an even lower denaturation temperature. By comparing hybrid DNA double helices with one strand contributed by each species—humans and chimpanzees, in this case—and determining their denaturation temperature, King and Wilson could infer the genetic distance (the extent of genetic divergence) between the two species.

### RESULTS

King and Wilson found that human–chimpanzee DNA molecules separated at a temperature approximately 1°C lower than the temperature at which human–human DNA molecules separate. They were able to calibrate this difference on the basis of studies of other species whose genetic distances were known from other methods. The DNA of humans differs from that of chimpanzees by approximately 1%.

#### CONCLUSION AND INTERPRETATION

King and Wilson noted the discrepancy between the extent of genetic divergence (small) and the extent of anatomical and behavioral divergence (large) between humans and chimpanzees. They suggested that one way in which relatively little genetic change could produce extensive phenotypic change is through differences in gene regulation ([Chapter 18](#)). A small genetic change in a control region responsible for switching a gene on and off might have major consequences for the organism.

#### FOLLOW-UP WORK

The genome sequences of the chimpanzee (completed in 2005) and the human (completed in 2003) allow us to compare the two sequences directly, and these data confirm King and Wilson's observations.

SOURCE King, M.-C., and A. C. Wilson. 1975. "Evolution at Two Levels in Humans and Chimpanzees." *Science* 188:107–116.

One of their methods of measuring molecular differences between species relied on DNA–DNA hybridization ([Chapter 12](#)). Two complementary strands of DNA in a double helix can be separated by heating the sample. If the two strands are not perfectly complementary, as occurs in the case of a base-pair mismatch (for example, a G paired with a T rather than with a C), less heat is required to separate the strands. King and Wilson used this observation to examine the differences between a human strand and the corresponding chimpanzee strand. They inferred the extent of DNA sequence divergence from the melting temperature and made a striking discovery: human DNA and chimpanzee DNA differ in sequence by just 1%.

King and Wilson's conclusions have proved robust as ever more powerful techniques have been applied to the comparison of human

and chimpanzee DNA. Today, after the entire human and chimpanzee genomes have been sequenced and the differences between the two sequences have literally been counted, the figure of 1% still approximately holds. Genome sequencing studies give us superbly detailed information on the differences and similarities between the two genomes, revealing regions that are present in one species but not in the other, and which parts of the genomes have evolved more rapidly than others.

Because the amount of sequence difference is correlated with the length of time the two species have been isolated, we can estimate that the split between the human and chimpanzee lineages occurred approximately 5–7 million years ago. All of the extraordinary characteristics that set our species apart from the rest of the natural world—those attributes that are ours and ours alone—arose in just this short span of time.

## The fossil record gives us direct information about our evolutionary history.

Molecular analysis is a powerful tool for comparing species and populations within species. It allows us to compare humans and chimpanzees and the differences among groups of humans or groups of chimpanzees. However, for a full picture of human evolution, we must turn to fossils ([Chapter 22](#)).

For the first several million years of human evolution, all the fossils

from the human lineage are found in Africa. This fact is not surprising. Darwin himself noted that it was likely that the human lineage originated there, as humans' two closest relatives, chimpanzees and gorillas, live only in Africa. Fossil material varies in quality, and a great deal of ingenuity is often required to reconstruct the appearance and attributes of an individual from fragmentary fossil material. It is difficult to ascertain whether two fossil specimens with slight differences belong to the same or different species. And, of course, the ability to interbreed, the criterion that researchers typically use to define a species ([Chapter 21](#)), cannot be determined from fossils. As a result, experts often disagree over the details of the human fossil record, such as whether a specimen belongs to a particular species. Despite these areas of uncertainty, we can draw several general conclusions.

The many different species, including modern humans, that have arisen on the human side of the split since the human/chimpanzee common ancestor are called [hominins](#). The earliest known hominin is *Sahelanthropus tchadensis* ([Fig. 23.4](#)). Discovered in Chad in 2002, the skull of *S. tchadensis* combines both modern (human) and ancestral features. Dated to approximately 7 million years ago, this species had a chimpanzee-sized brain but hominin-type brow ridges. *S. tchadensis* probably lived shortly after the split between the hominin and chimpanzee lineages, although this conclusion is controversial because of difficulties in interpreting whether a fossil is part of a newly diverged lineage or just another specimen of the ancestral lineage.

Source: Sabena Jane Blackbird/Alamy.

FIG. 23.4 The skull of *Sahelanthropus tchadensis*. This skull, which is about 7 million years old and was found in Chad, has both human and chimpanzee features.

Another important early hominin, dating from about 4.4 million years ago, is *Ardipithecus ramidus* from Ethiopia. This individual, known as [Ardi](#), was capable of walking upright, using two legs on the ground but all four limbs in the trees.

An unusually complete early hominin fossil dating from around 3.2 million years ago is [Lucy](#). She was found in 1974 at Hadar, Ethiopia, and was fully [bipedal](#), habitually walking upright ([Fig. 23.5](#)). The fossil's name comes from the Beatles' song "Lucy in the Sky with Diamonds," which was playing in the paleontologists' field camp when she was unearthed. Lucy was a member of the species *Australopithecus afarensis* and was much smaller than modern humans, less than 4 feet tall, and had a considerably smaller brain (even when the difference in

body size is taken into consideration). In many ways, then, Lucy was similar to the common ancestor of humans and chimpanzees, except that she was bipedal.

Source: The Natural History Museum, London/The Image Works.

FIG. 23.5 Lucy, a specimen of *Australopithecus afarensis*. Lucy was fully bipedal, establishing that the ability to walk upright evolved at least 3.2 million

years ago.

Remarkably, many different hominin species were living in Africa at the same time. [Fig. 23.6](#) shows the main hominin species and the longevity of each in the fossil record, along with suggested evolutionary relationships among the species. Note that all hominins have a common ancestor, but not all of these groups lead to modern humans. The *Homo* lineage ultimately produced modern humans, *Homo sapiens*. Other branches of the hominin tree ultimately went extinct.

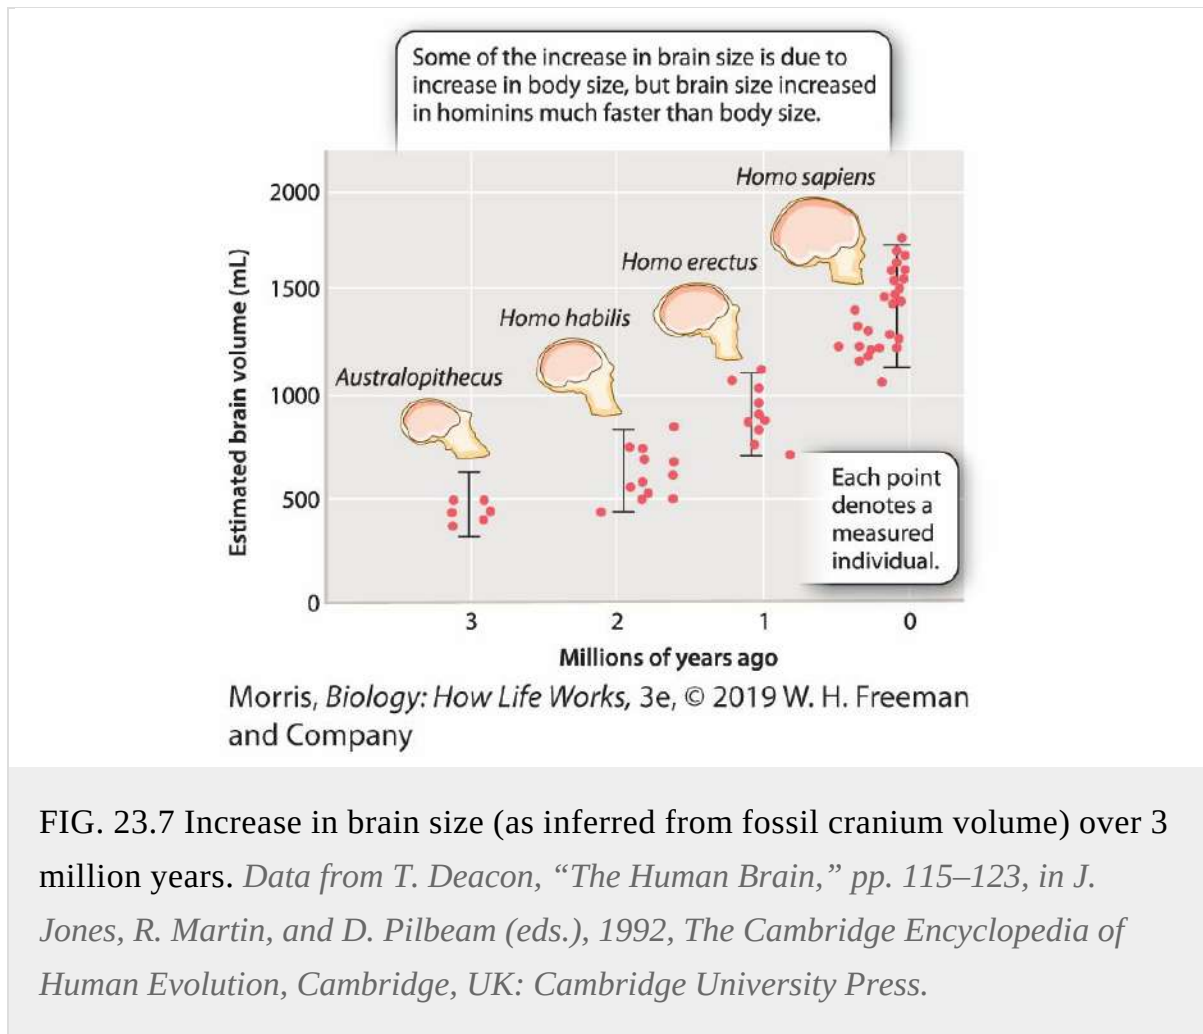

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 23.6 Hominin lineages. Three main lineages, *Ardipithecus*, *Australopithecus*, and *Homo*, existed at various and sometimes overlapping times in history. Sources: Data from R. G. Klein, 2009, *The Human Career*, Chicago: University of Chicago Press, p. 234; *Homo floresiensis* skull from R. D. Martin, A. M. MacLarnon, J. L. Phillips, L. Dussubieux, P. R. Williams, and W. B. Dobyns, 2006, Comment on "The Brain of LB1, *Homo floresiensis*," *Science* 312:999.

A number of trends can be seen when we look over the hominin fossil record. For example, body size increased. Most striking is the

increase in size of the cranium and therefore, by inference, size of the brain, as shown in [Fig. 23.7](#).

The earliest hominin fossils found in Asia are approximately 2 million years old, indicating that at least one group of hominins had ventured out of Africa by then. The individuals that first left Africa were members of a species that is sometimes called *Homo ergaster* and sometimes *Homo erectus*. The confusion stems from the controversies that surround the naming of fossil species. Some researchers contend that *H. ergaster* is merely an early form of *H. erectus*. Here, we designate this first hominin *Homo ergaster* and a later descendant species *H. erectus* (see [Fig. 23.6](#)). The naming details, however, are

relatively unimportant. What matters is that some hominins first colonized areas beyond Africa about 2 million years ago.

Another hominin species was *Homo neanderthalensis*, whose fossils appear in Europe and the Middle East. [Neanderthals](#) represent a second hominin exodus from Africa dating from around 600,000 years ago ([Fig. 23.8](#)). Thicker boned than modern humans, and with flatter heads that contained brains about the same size as, or slightly larger than, ours, Neanderthals disappeared around 30,000 years ago. As we will see, genetic analysis suggests that this group likely interbred with our own group, *Homo sapiens*, so this disappearance was perhaps not as complete as the fossil record suggests.

FIG. 23.8 Skeletons of *Homo neanderthalensis* and *Homo sapiens*. Neanderthals disappeared from Europe about 30,000 years ago, approximately 10,000 years after a group of modern humans called Cro-Magnon first appeared in Europe.

Another hominin species became extinct only about 12,000 years ago: *H. floresiensis*, known popularly as the Hobbit. *H. floresiensis* is peculiar. Limited to the Indonesian island of Flores, adults of this

species were only a little more than 3 feet tall. Some experts have suggested that *H. floresiensis* is not a genuinely distinct species, but rather an aberrant *H. sapiens*. Plenty of morphological evidence, however, suggests that *H. floresiensis* is a distinct species derived from an archaic *Homo* species, probably *H. erectus* (**Fig. 23.9**). Mammals often evolve small body size on islands because of the limited availability of food.

FIG. 23.9 Phylogenetic tree of recent hominins. When modern humans departed Africa about 60,000 years ago, they encountered and interbred with Neanderthals and Denisovans, groups derived from an earlier African exodus.

### Self-Assessment Questions

1. Did humans evolve from chimpanzees? Explain.
2. Describe the evidence suggesting that chimpanzees are the

closest living relatives of humans.

3. What can we learn about human evolution from the hominin fossil record that we *cannot* learn from analyses of living species?

## 23.2 AFRICAN ORIGINS

From the wealth of fossil evidence, it's clear that modern humans first evolved in Africa. But for a while the timing of this event was unclear. Can all modern humans, *Homo sapiens*, date their ancestry to early hominins in Africa that migrated out and spread around the world about 2 million years ago? Or did the groups that left Africa ultimately go extinct, so that modern humans evolved from a group of hominins in Africa that migrated out much more recently? Molecular studies helped to answer this question.

### Studies of mitochondrial DNA reveal that modern humans evolved in Africa relatively recently.

For a long time, it was argued that modern humans derive from the *Homo ergaster* (or *H. erectus*) populations that spread around the world starting around the time of the early migration out of Africa 2 million years ago. This idea is called the [multiregional hypothesis](#) of human origins because it implies that different *Homo ergaster* populations throughout Africa and Eurasia evolved in parallel, with some limited gene flow among them, each producing modern *H. sapiens* populations. In short, the multiregional hypothesis asserts that racial differences among humans would have evolved over 2 million years in different geographic locations.

This idea was overturned in 1987 by a study that suggested instead that modern humans arose much more recently from *Homo ergaster* descendants that remained in Africa (sometimes called *Homo*

*heidelbergensis*; see [Fig 23.6](#)). According to this hypothesis, all modern humans are descended from an African common ancestor dating from approximately 200,000 years ago. This newer idea is called the [out-of-Africa hypothesis](#) of human origins.

To test these two hypotheses about human origins, Rebecca Cann, a student in Allan Wilson's laboratory, analyzed DNA sequences to reconstruct the human family tree. Specifically, she studied sequences of a segment of mitochondrial DNA from people living around the world ([Fig. 23.10](#)).

#### HOW DO WE KNOW?

### FIG. 23.10

## When and where did the most recent common ancestor of all living humans live?

#### BACKGROUND

With the availability of DNA sequence analysis tools, it became possible to investigate human prehistory by comparing the DNA of living people from different populations.

#### HYPOTHESIS

The multiregional hypothesis of human origins suggests that our most recent common ancestor was living at the time *Homo ergaster* populations first left Africa, about 2 million years ago.

#### METHOD

In the late 1980s, American Rebecca Cann compared mitochondrial DNA (mtDNA) sequences from 147 people from around the world. This approach required a substantial amount of mtDNA from each individual, which Cann acquired by collecting placentas from women after childbirth.

Instead of sequencing the mtDNA, Cann inferred differences among sequences by digesting the mtDNA with different restriction enzymes, each of which cuts DNA at a specific sequence ([Chapter 12](#)). If the specific sequence is present, the enzyme cuts. If any base in the recognition site of the restriction enzyme has changed in an individual and the specific sequence is *not* present, the enzyme does not cut. The resulting fragments were then separated by gel electrophoresis. By using 12 different enzymes, Cann was able to assay a reasonable proportion of all the mtDNA sequence variation present in each sample.

[Fig. 23.10a](#) is a sample dataset for four people and a chimpanzee. There are seven varying restriction sites.

#### ANALYSIS

Cann converted the data into a family tree ([Fig. 23.10b](#)) by using shared derived characters, as described in [Chapter 22](#). By mapping the pattern of changes in this way, Cann was able to reconstruct the phylogenetic relationships of the mtDNA sequences. For example, the derived “cut” state at restriction site 1 shared by the East African, Japanese, and Native American sequences implies that the three groups have a common ancestor in which a mutation created the new restriction site.

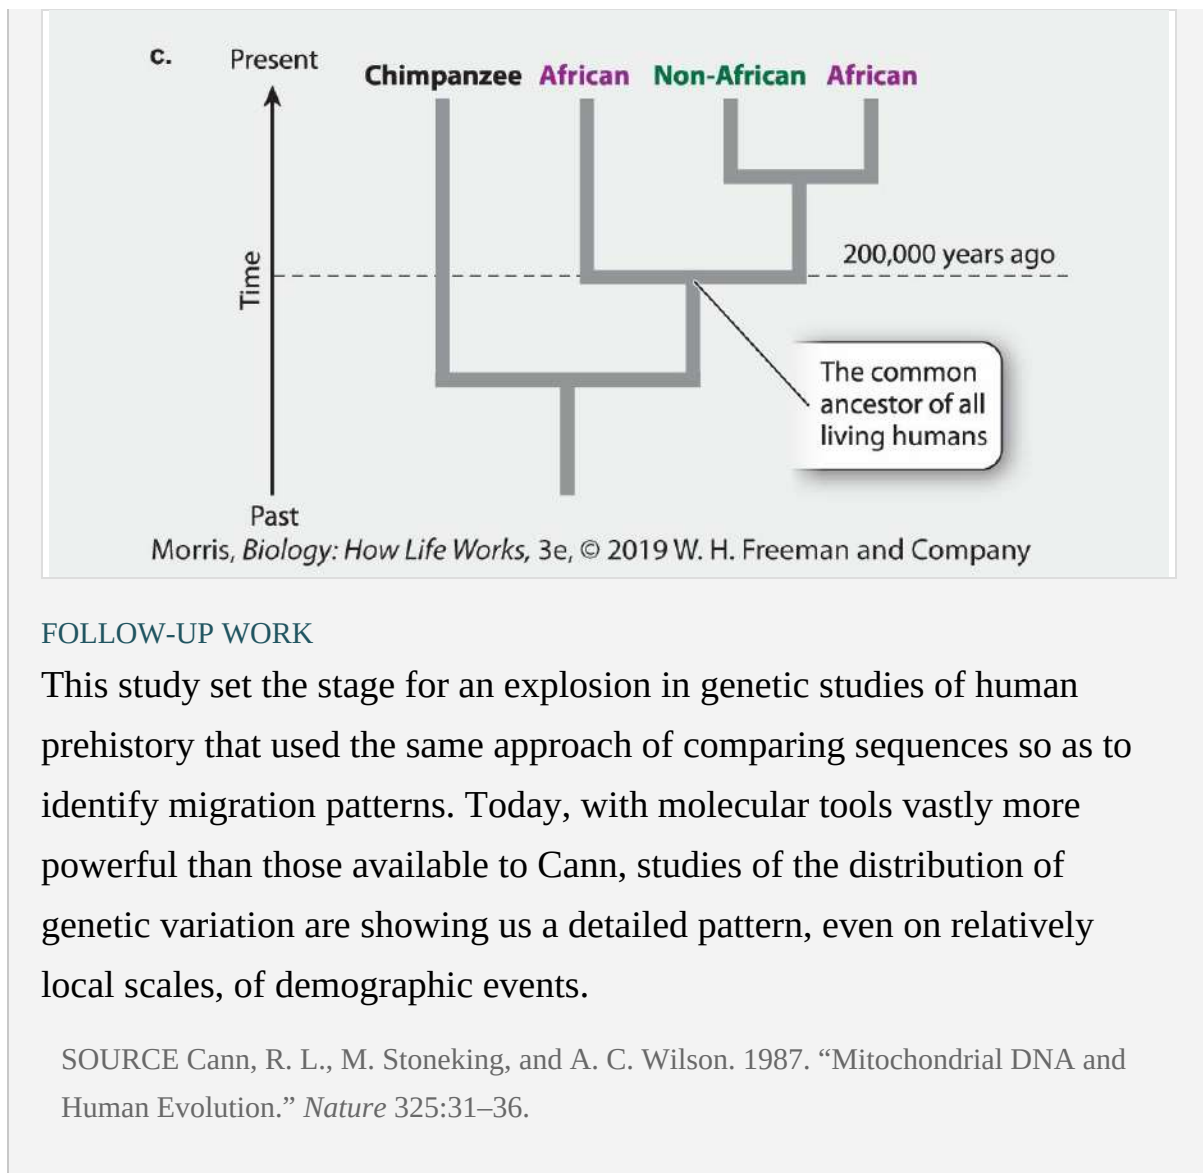

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

## RESULTS AND CONCLUSION

A simplified version of Cann's phylogenetic tree based on mtDNA is shown in [Fig. 23.10c](#). Modern humans arose relatively recently in Africa, and their most common ancestor lived about 200,000 years ago. The multiregional hypothesis is rejected. Also, Cann's data revealed that all modern humans who lived or live outside of Africa derive from within the African family tree, implying that *H. sapiens* left Africa relatively recently. The Cann study gave rise to the out-of-Africa hypothesis of human origins.

**Mitochondrial DNA (mtDNA)** is a small circle of DNA, approximately 17,000 base pairs long, that is found in every mitochondrion ([Chapter 16](#)). Cann chose to study mtDNA for several reasons. Although a typical cell contains a single nucleus with just two copies of nuclear DNA, each cell has many mitochondria, each carrying multiple copies of mtDNA; thus, mtDNA is much more abundant than nuclear DNA and, therefore, easier to extract. More important, however, is mtDNA's mode of inheritance. All of a person's mtDNA is inherited from their mother as part of the egg she produces

because sperm do not contribute mitochondria to the zygote. As a consequence, there is no opportunity for genetic recombination between different mtDNA molecules and the only way in which sequence variation can arise is through mutation. In nuclear DNA, by contrast, differences between two sequences can be introduced by both mutation and recombination ([Chapter 20](#)). Recombination obscures genealogical relationships because it mixes segments of DNA with different evolutionary histories.

Mitochondrial DNA sequences offered Cann a clear advantage. With sequence information from the mtDNA of 147 people from around the world, Cann reconstructed the human family tree ([Fig. 23.10](#)). The tree contained two major surprises. First, the two deepest branches—the ones that come off the tree earliest in time—are African. All non-Africans are branches off the African tree. The implication is that *Homo sapiens* evolved in Africa; only afterward did populations migrate out of Africa and become established elsewhere. This finding contradicted the expectations of the multiregional theory, which suggested that *Homo sapiens* evolved independently in different locations throughout the Old World.

Second, the tree is remarkably shallow. That is, even the most distantly related modern humans have a relatively recent common ancestor. By calibrating the rate at which mutations occur in mtDNA, Cann was able to estimate the time back to the common ancestor of all modern humans as about 200,000 years. Subsequent analyses have somewhat refined this estimate, but the key message has not changed: the data contradict the multiregional hypothesis, which predicted a

number closer to 2 million years.

## Studies of the *Y* chromosome provide independent evidence for a recent origin of modern humans.

Given that 200,000 years ago is 10 times more recent than 2 million years ago, this updated estimate represents a revolution in our understanding of human prehistory. Perhaps it is risky to make such major claims on the basis of a single study; maybe there's something peculiar about mtDNA, and it doesn't offer an accurate picture of the human past.

To find independent evidence for a recent origin of modern humans in Africa, another dataset was required. One such dataset comes from studies of the *Y* chromosome, another segment of human DNA that does not undergo recombination ([Chapter 16](#)). When an approach similar to that employed by Cann was used to reconstruct the human family tree using *Y* chromosome DNA sequences, the result was completely in agreement with the mtDNA result: the human family is young, and it arose in Africa.

## Neanderthals disappear from the fossil record as modern humans appear, but have contributed to the modern human gene pool.

If we exclude *H. floresiensis*, the last of the nonmodern humans were

the Neanderthals (see [Fig. 23.9](#)), who lived in Europe and Western Asia until about 30,000 years ago. What happened to them? Were they eliminated by the first population of *Homo sapiens* to arrive in Europe (a group named [Cro-Magnon](#) after the site in France from which specimens were first described)? Or did Neanderthals interbreed with the Cro-Magnons, and, if so, does that mean that Neanderthals should be included among modern humans' direct ancestors? Indeed, if modern humans interbred with Neanderthals and our definition of species is based on reproductive isolation ([Chapter 21](#)), perhaps we should consider *H. sapiens* and *H. neanderthalensis* as belonging to the same species.

In 1997, it appeared that we had a clear answer to this question. Matthias Krings, working in Svante Pääbo's lab in Germany, extracted intact stretches of mtDNA from 30,000-year-old Neanderthal bone. If Neanderthals had interbred with modern humans' ancestors, we would expect to see evidence in the form of Neanderthal mtDNA in our own gene pool. In fact, the Neanderthal mtDNA sequence was strikingly different from that of modern humans. That we see nothing even close to the Neanderthal mtDNA sequence in modern humans strongly suggests that Neanderthals did not interbreed with our ancestors.

This conclusion was subsequently reversed following remarkable technological advances that permitted Pääbo and others to sequence the entire Neanderthal genome (rather than just Neanderthal mtDNA). Careful population genetic analysis reveals that the ancestors of modern humans did interbreed with Neanderthals, and that 1% to 4% of the genome of every non-African is derived from that species.

A new scenario emerged to explain this discovery: as populations of our ancestors headed from Africa into the Middle East, they encountered Neanderthals, and it was then, before modern humans had spread out across the world, that interbreeding took place. Remarkably, ancient DNA analysis has further revealed that early non-African *Homo sapiens* did not interbreed only with Neanderthals. Another group of Eurasian hominins, relatives of Neanderthals known as Denisovans after the Siberian cave in which their remains were found, also contributed genetically to some modern human populations, especially indigenous people from Australasia (see [Fig 23.9](#)).

How can we reconcile the two apparently contradictory results about the contributions of Neanderthals to the modern human gene pool? The mtDNA study of Neanderthals indicates there was no genetic input from Neanderthals in modern humans, but the whole-genome study suggests that there was. One possible solution lies in the difference in patterns of transmission between mtDNA and genomic material ([Chapter 16](#)). Recall that mtDNA is maternally inherited because sperm do not contribute mitochondrial material. Your mtDNA, whether you are male or female, is derived solely from your mother. Therefore, it is possible that the Neanderthal mtDNA lineage has been lost through genetic drift ([Chapter 20](#)).

An alternative explanation is that the discrepancy in the ancient DNA stems from a sex-based difference in interbreeding. If Neanderthal females did not interbreed with our ancestors, Neanderthal mtDNA would not have entered the modern human gene pool. If only male Neanderthals interbred with our ancestors, we would expect

exactly the pattern we observe: no Neanderthal mtDNA in modern humans, but Neanderthal genomic DNA in the modern human gene pool.

Regardless of the details of what happened when modern humans, Neanderthals, and Denisovans encountered one another, one thing is clear: genomic sequencing demands that we reimagine the ancestry of a large portion of the human population. Every non-African on the planet is part Neanderthal, albeit a very small part, and many non-Africans can count Denisovans among their ancestors as well.

#### Self-Assessment Questions

4. What are the multiregional and out-of-Africa hypotheses, and what are their respective predictions about the common ancestor of all humans that are living today?
5. How do studies of mitochondrial DNA and the Y chromosome support the out-of-Africa hypothesis of human origins?
6. How are genetic data consistent with the possibility that only male Neanderthals interbred with our ancestors?

## 23.3 HUMAN TRAITS

Many extraordinary changes in anatomy and behavior have occurred in the 5–7 million years since our human lineage split from the lineage that gave rise to the chimpanzees. Fossils tell us a great deal about those changes, especially high-quality material such as Lucy and Ardi. In general, though, hominin fossils are hard to come by and there is a lot of speculation. Speculation is especially rampant when we try to explain the reasons behind the evolution of a particular trait. Why, for example, did language evolve? It is easy enough to think of a scenario in which natural selection favors some ability to communicate—maybe language arose to facilitate group hunting. Plenty of plausible ideas on the subject have been proposed, but, in most cases, no evidence is available to support them. Thus, it is impossible to declare a winner among competing hypotheses. Nevertheless, we can be confident that the events that produced language occurred in Africa. Moreover, through paleontological studies of past environments, we can conclude that humans evolved in an environment similar in many ways to today's East African savanna.

### Bipedalism was a key innovation.

The shift from walking on four legs to walking on two legs was probably one of the first changes in our lineage. Many primates are partially bipedal—chimpanzees, for example, may be observed knuckle-walking—but humans are the only living species that is wholly bipedal. Lucy, dating from about 3.2 million years ago, was already bipedal, and, 4.4 million years ago, Ardi was partially bipedal. We can further refine our estimate of when full bipedalism arose from

the evidence of a trace fossil. A set of 3.5-million-year-old fossil footprints discovered in Laetoli, Tanzania, reveal a truly upright posture.

Becoming bipedal is not simply a matter of standing up on hind legs. The change required substantial shifts in a number of basic anatomical characteristics, described in [Fig. 23.11](#).

**Foramen magnum**

The foramen magnum, the hole in the skull through which the spinal cord passes, is repositioned so that the human skull balances directly on top of the vertebral column.

**Spine**

The human spine is S-shaped so weight is directly over the pelvis.

**Legs**

The pelvis is extensively reconfigured for an upright posture, with internal organs over it. Legs are longer to enable long stride length for efficient locomotion and their anatomy altered so the legs are directly under the body.

**Feet**

The foot is narrower and has a more developed heel and larger big toe, which contributes to a springier foot.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 23.11 The shift from four to two legs. Anatomical changes were required for the shift to bipedalism, especially in the structure of the skull, spine, legs, and feet.

Why did hominins become bipedal? Maybe it gave them access to berries and nuts located high on a bush. Maybe it allowed them to scan the vicinity for predators. Maybe it made long-distance travel easier. Whatever the reason for its emergence, bipedalism freed our ancestors' hands. No longer did they need their hands for locomotion, so for the first time there arose the possibility that specialized hand function could evolve. Most primates have some kind of opposable thumb, but the human version is much more dexterous. The human thumb has three muscles that are not present in the thumb of chimpanzees, which allow much finer motor control of the thumb. Tool use, which is present but crude in chimpanzees, can be much more subtle and sophisticated with a human hand.

Exactly when sophisticated tool use arose is controversial, but it is indisputable that bipedalism contributed to its development. Similarly, the ability to manipulate food with the hands, and to carry material using the hands rather than the mouth, likely permitted the evolution of the human jaw—indeed, the entire facial structure—in such a way that language became a possibility.

## Adult humans share many features with juvenile chimpanzees.

King and Wilson's 1975 discovery that the DNA of humans and of chimpanzees are 99% identical has recently been confirmed by DNA

sequence comparison of the human and chimpanzee genomes. It turns out that the two genomes are extraordinarily similar: all our genes are also present in the chimpanzee, and gene sequences in humans and in chimpanzees are extremely similar, suggesting that the functions of the proteins our genes code for are the same. If humans and chimpanzees are so similar, how can we account for the extensive differences between the two species?

In their original paper, King and Wilson suggested that much of the most significant evolution along the hominin lineage came about through changes in the regulation of genes ([Chapter 18](#)). A small change—one that causes a gene to be transcribed at a different stage of development, for example—can have a major effect. In essence, King and Wilson introduced a model in which small changes in the software have a major impact even though the basic hardware is the same.

One of the gene-regulatory pathways that changed may be responsible for human [neoteny](#), the long-term evolutionary process in which the timing of development is altered so that a sexually mature organism retains the physical characteristics of the juvenile form. In keeping with King and Wilson's idea, this shift in development could conceivably be achieved with relatively little genetic change. All that it might take would be a few changes to the regulatory switches that control the timing of development.

As early as 1836, French naturalist Étienne Geoffroy Saint-Hilaire noted that a young orangutan on exhibit in Paris looked considerably more like a human than the adult of its own species ([Fig. 23.12](#)).

Several human attributes support this model, including heads that are large relative to bodies (and with correspondingly large brains), a feature of juvenile great apes. A second human attribute is lack of body hair. The juveniles of other great apes are not as hairless as humans, but they're considerably less hairy than adult apes. A third attribute is the position of the foramen magnum at the base of the skull (see [Fig. 23.11](#)). In primate development, the foramen magnum starts off in the position it occupies in the adult human and then, in nonhuman great apes, migrates toward the back of the skull. Adult humans have retained the juvenile great ape foramen magnum position. Finally, it has been suggested that human mentality, with its questioning and playfulness, is equivalent in many ways to that of a juvenile ape rather than to that of the comparatively inflexible adult ape.

Russell Watkins/Shutterstock.*

FIG. 23.12 A juvenile and an adult orangutan. Humans look more like juvenile orangutans than like adult orangutans, suggesting that humans may be neotenous great apes.

# Humans have large brains relative to body size.

In mammals, brain size is typically correlated with body size. Humans are relatively large-bodied mammals, but our brains are large even for our body size ([Fig. 23.13](#)). It is our large brains that have allowed our species' success, extraordinary technological achievements, and at times destructive dominion over the planet.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 23.13 Brain size plotted against body size for different species. Humans have large brains for their body size. Data from Fig. 2.4, p. 44, in H. J. Jerison, 1973, *Evolution of the Brain and Intelligence*, New York: Academic Press.

Which factors acted as selective pressure for the evolution of the large human brain? Again, speculation about this question runs

rampant. However, because a large brain is metabolically expensive to produce and to maintain, we can conclude that the brain has adaptive features that natural selection acted to favor. What are these selective factors? Here are some possibilities:

- *Tool use.* Bipedalism permitted the evolution of manual dexterity, which in turn requires a complex nervous organization if hands are to be useful.
- *Social living.* Groups require coordination, and coordination requires some form of communication and the means of integrating and acting upon the information conveyed. One scenario, for example, sees group hunting as critical in the evolution of the brain: natural selection favored those individuals who cooperated best as they pursued large prey.
- *Language.* Did the evolution of language drive the evolution of large brains? Or did language arise as a result of having large brains? Again, we will probably never know, but it is tempting to speculate that the brain and our extraordinary powers of communication evolved in concert.

Probably, as with bipedalism, no single factor drove the development of humans' large brain, but rather a combination of factors worked together to result in the evolution of large brain size. We tend to focus on brain size because it is a convenient stand-in for mental power and because we can measure it in the fossil record by making the reasonable assumption that the volume of a fossil's cranium reflects the size of its brain. Of course, our minds are not solely the products of larger brains. Instead, the reorganization of

existing structures and pathways is the more important product of the evolution of the brain. Not only was the brain expanding over those 5–7 million years of human evolution, but it was also being rewired.

We can be sure that the human brain evolved through natural selection because it is such a metabolically costly organ. Although the brain contributes only 2% of a human's weight, it accounts for 20% of the body's metabolic budget. The evolutionary advantages of a large brain must be substantial enough to offset this cost. What we have today, as a result, is a learning machine capable of generating many more skills and abilities than just those that directly enhance evolutionary fitness. For example, let's assume that the brain evolved to make group hunting more efficient. Although the larger brain does indeed enhance our ability to hunt together, numerous by-products of this brain then take its abilities beyond just hunting. Making art, for instance, has nothing to do with group hunting, yet the brain allows us to do it. A brain that evolved for an essential but mundane task like group hunting lies at the heart of much that is wonderful about humanity.

## The human and chimpanzee genomes help us identify genes that make us human.

The key genetic differences between humans and chimpanzees must lie in the approximately 1% of protein-coding DNA sequence that differs between the two genomes. What do we see when we compare human and chimpanzee genomes?

One gene that has attracted a lot of interest is *FOXP2*, a member of a large family of evolutionarily conserved genes that encode transcription factors that play important roles in development. People with mutations in *FOXP2* often have difficulty with speech and language. Interestingly, laboratory animals whose *FOXP2* gene has been knocked out also have communication impairments. Songbirds are less capable of learning new songs, and the high-frequency “songs” of mice are disrupted. In addition to its effects on the brain, *FOXP2* plays a role in the development of many tissues.

Studies of the *FOXP2* gene’s amino acid sequence reveal a pattern of extreme conservation. These amino acid sequences in mice and chimpanzees, whose most recent common ancestor lived about 75 million years ago, differ by a single amino acid ([Fig. 23.14](#)). However, two amino acids are present in humans but absent in chimpanzees. Studies of Neanderthal DNA have shown that Neanderthals possessed the modern human version of *FOXP2*. The presence of the same version of the gene in both species suggests that the differences arose in the hominin line before the split between our species and Neanderthals, which occurred at least 600,000 years ago.

Studies of *FOXP2* give us a glimpse into the genetic architecture of the biological traits that are likely to be important in the determination of “humanness.” Those two differences in amino acid sequence are intriguing, but they do not make an organism a human. Substitute the human *FOXP2* gene into a mouse and you will not get a talking mouse. The critical genetic differences are many, subtle, and interacting.

#### Self-Assessment Questions

7. What are four anatomical differences between chimpanzees and humans that facilitated walking upright?

8. Given the high genetic similarity of humans and chimpanzees, how might gene-regulatory pathways help us account for the differences we see between the two species?
9. What are three possible selective factors underlying the evolution of large brains in our ancestors?
10. The *FOXP2* gene is sometimes called the “language gene.” Why is this name inaccurate?

## 23.4 HUMAN GENETIC VARIATION

So far, we have treated humans as all alike, and, in many ways, we are. But there are also many differences from one person to the next. Those differences ultimately have two sources: genetic variation and differences in environment ([Chapter 17](#)). For example, a person may be born with dark skin, or a person born with pale skin may acquire darker skin—a tan—in response to exposure to sun.

### Humans have very little genetic variation.

The differences we see from one person to the next are deceptive. Despite appearances, ours is not the most genetically variable species on Earth. While it is certainly true that everyone alive today (except for identical twins) is genetically unique, our species is actually rather low in overall amounts of genetic variation. Modern estimates based on comparisons of many human DNA sequences indicate that, on average, about 1 in every 1000 base pairs differs among individuals (that is, our level of DNA variation is 0.1%). That's about 10 times less genetic variation than occurs in fruit flies (which nevertheless all look the same to us) and about two to three times less than is found in Adélie penguins, which look strikingly similar to one another (see [Fig. 20.1](#)).

Why, then, are humans all so phenotypically different if there is so little genetic variation in our species? Given the large size of our genome, a level of variation of 0.1% translates into a great many genetic differences. Our genome consists of approximately 3 billion

base pairs, so 0.1% variation means that 3 million base pairs differ between any two people chosen at random. Many of those differences are in noncoding DNA, but some fall in regions of DNA that encode proteins or regulatory regions and, therefore, influence the phenotype. When those mutations are reshuffled by recombination, the result is the vast array of genetic combinations present in the human population.

## The prehistory of humans influenced the distribution of genetic variation.

The reasons for our species' relative lack of genetic variation compared to other species lie in prehistory, and factors affecting the geographical distribution of that variation also lie in the past. Studies of the human family tree inspired by Rebecca Cann's original mtDNA analysis paint a detailed picture of how our ancestors colonized the planet and how that process affected the distribution of genetic variation across populations today. Detailed analyses of different populations, often using mtDNA or Y chromosomes, allow us to reconstruct the history of human population movements.

As we have seen, *Homo sapiens* arose in Africa. Genetic analyses indicate that perhaps 60,000 years ago, populations started to venture out through the Horn of Africa into the Middle East ([Fig. 23.15](#)). The first phase of colonization took our ancestors through Asia and into Australia about 50,000 years ago. Archaeological evidence indicates that it was not until about 15,000 years ago that the first modern humans crossed from Siberia to North America to populate the New World.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 23.15 Human migratory routes. Tracking the spread of mitochondrial DNA mutations around the globe allows us to reconstruct the colonization history of our species. Data from Fig. 6.18, p 149, in D. J. Futuyma, 2009, *Evolution*, 2nd ed., Sunderland, MA: Sinauer Associates.

Genetic analyses indicate that other colonizations occurred even later. Despite its closeness to the African mainland, the first humans arrived in Madagascar only about 2000 years ago, and the colonists came from Southeast Asia, not Africa. Madagascar populations to this day bear the genetic imprint of this surprising Asian input. The Pacific Islands were among the last habitable places on Earth to be colonized during the Polynesians' extraordinary seaborne odyssey from Samoa, which began about 2000 years ago. Hawaii was colonized about 1500 years ago, and New Zealand only 1000 years ago.

By evolutionary standards, the beginning of the spread of modern humans out of Africa about 60,000 years ago is very recent. Consequently, differences have had relatively little time to accumulate

among regional populations. Indeed, most of the variation in human populations today arose in ancestral populations before any humans left Africa. When we compare levels of variation in a contemporary African population with that in a non-African population, such as Europeans or Asians, we find there is more variation in the contemporary African population. The individuals who left Africa 60,000 years ago to found populations in the Middle East and beyond were a relatively small sample of the total amount of genetic variation then present in the human population. Contemporary descendants of these populations who left Africa early in human history therefore began with less genetic variation, and that initial lower variation is reflected in their genetic profiles today.

## The recent spread of modern humans means that there are few genetic differences between groups.

Because the out-of-Africa migration was so recent, the genetic differences we see among geographical groups—sometimes called races—are actually quite minor. This fact is highly counterintuitive. People may note many superficial differences between a typical African and a typical European, such as skin color, facial form, and hair type, and assume that these superficial differences must reflect extensive genetic differences. This assumption made sense when the standard theory about the origin of modern humans was the multiregional one. If European and African populations had been geographically isolated from each other for as long as 2 million years, then it would make sense to expect significant genetic differences

among populations.

Isolated populations diverge genetically over time as different mutations occur and are fixed in each population. The longer two populations have been isolated from each other, the more genetic differences between them we would expect to see ([Chapter 20](#)). Isolation lasting 2 million years implies that the differences are extensive, whereas isolation for just 60,000 years suggests differences are relatively few. Patterns of genetic variation among different human populations support the hypothesis that human populations dispersed as recently as 60,000 years ago. What we see when we look at genetic markers—variable A's, T's, G's, and C's in human DNA—is that there is actually very little genetic differentiation among human populations scattered across the globe.

In short, there's a disconnect: different groups may look different, but, from a genetic perspective, they're not very different at all. Any two humans differ from each other by, on average, only 3 million base pairs. Statistical analyses show that approximately 85% of that genetic variation occurs within a population (for example, the Yoruba in West Africa); 8% occurs between populations within so-called races (for example, between the Yoruba and the Kikuyu, another African group); and the remaining 7% occurs between so-called races. The characteristics used to assess an individual's ethnicity, such as skin color, eye type, and hair form, are encoded by genetic variants that lie in that 7%. If Earth were threatened with destruction and only one population—the Yoruba, for example—survived, 85% of the total amount of human genetic variation that exists today would still be

present.

## Some human differences have likely arisen by natural selection.

Patterns of genetic variation in human populations are shaped by the set of evolutionary forces discussed in [Chapter 20](#). Neutral variants, for example, are subject to genetic drift, and, given the stepwise global colonization history of our species, it is likely that founder events have played a role as well.

Selection, too, has been important. For example, the genetic variants affecting traits we can easily see are an especially prominent feature of the 7% of human genetic variation that occurs between so-called races. If we look at other genetic variants, which don't affect traits that we can see, there is little or no racial pattern. A contemporary dark-skinned African is as likely to have a particular base-pair mutation in a randomly chosen gene as a contemporary fair-skinned European. So why are visible traits so markedly different among groups while other traits are not? Given the short amount of time (by evolutionary standards) since all *Homo sapiens* were in Africa, it is likely that the differences we see between groups are the product of selection.

People with dark skin tend to originate from areas in lower latitudes with high levels of solar radiation, whereas people with light skin tend to originate from areas in higher latitudes (near the equator) with low levels of solar radiation (toward the poles). It is likely that natural selection is responsible for the differences in pigmentation between these populations. Assuming that the ancestors of non-African

populations were relatively dark-skinned, which selective factors might account for the loss of pigmentation among populations that now live at higher latitudes?

One likely factor is an essential vitamin, vitamin D, that is particularly important in childhood because it is needed for the production of bone. A deficiency of vitamin D can result in the skeletal malformation known as rickets. The body can synthesize vitamin D, but the process requires ultraviolet (UV) radiation. Heavily pigmented skin limits the entry of UV radiation into cells, thereby limiting the production of vitamin D. This does not present a difficulty in parts of the world where there is plenty of sunlight, but it can be problematic in regions of low sunlight. Presumably, natural selection favored lighter skin in the ancestors of populations from higher latitudes because lighter skin promotes the production of vitamin D.

A second likely factor is folate, another vitamin. Folate is necessary for normal embryonic development, and a deficiency of folate can lead to certain birth defects. UV radiation can break down folate, so natural selection favors darker skin in areas where there is a lot of sunlight, such as near the equator. Here, too, there is the danger of UV damage both to skin cells and to the DNA molecules they contain, with cancers such as melanoma a possible outcome. Again, skin pigmentation plays a key protective role. Thus, UV radiation is a double-edged sword: it breaks down one essential vitamin (folate) and damages DNA, but is essential for the production of another vitamin, D. Skin color across the globe represents a balance between these opposing selective pressures.

Attempts have been made to identify the adaptive value of other visible differences among groups, such as facial features. It is possible that natural selection played a role in the evolution of these differences, but an alternative explanation, originally suggested by Charles Darwin, is more compelling: sexual selection ([Chapter 20](#)). As we have seen, there is an apparent mismatch between the extent of differences among groups in visible characters, such as facial features, and the overall level of genetic differences between human groups. Sexual selection can account for this mismatch because it operates solely on characteristics that can readily be seen—think of the peacock’s tail. As we learn more about the genetic underpinnings of the traits in question, we will be able to investigate directly the factors responsible for the differences we see among groups.

---

#### CASE 4 MALARIA: COEVOLUTION OF HUMANS AND A PARASITE

## Which human genes are under selection for resistance to malaria?

We see evidence of regional genetic variation in response to local challenges, especially those posed by disease. Malaria, for example, is largely limited to warm climates because it is transmitted by a species of mosquito that can survive only in these regions. Historically, this disease has been devastating in Africa and the Mediterranean. As we saw in [Chapter 20](#), the sickle allele of hemoglobin, *S*, has evolved to be present at high frequencies in these regions because in heterozygotes it

confers some protection against the disease. But in homozygotes, the S allele is highly detrimental because it causes sickle-cell anemia. Homozygotes for the allele encoding normal hemoglobin are also at a disadvantage because they are entirely unprotected from the parasite.

The S allele is beneficial only in the presence of malaria. If there is no malaria in an area, the S allele is disadvantageous, so natural selection presumably acted rapidly to eliminate it in the ancestors of Europeans when they arrived in malaria-free regions. The continued high frequency of the S allele in contemporary Africans, in some Mediterranean populations, and in populations descended recently from Africans (such as African-Americans) is, however, a reflection of the response of natural selection to a regional disease.

The hemoglobin genes are not the only genes that are under selection for resistance to malaria. *Glucose-6-phosphate dehydrogenase (G6PD)*, a gene involved in glucose metabolism, is one of several other genes implicated. People who are heterozygotes for a mutation in the *G6PD* gene—and therefore have a G6PD enzyme deficiency—can develop severe anemia when they eat certain foods, most notably fava beans (hence, the condition is called favism). People who are heterozygotes for a mutation in the *G6PD* gene also have increased resistance to malaria, apparently because they are better at clearing infected red blood cells from their bloodstream. In areas where malaria is common, the advantage of malaria resistance offsets the disadvantage of favism.

Detailed evolutionary analysis of mutations in *G6PD* shows that

favism has arisen multiple times, each time selectively favored because of its role in the body's response to the malaria parasite. As expected, favism, like sickle-cell anemia, is mainly a feature of populations in malarial areas or of populations whose evolutionary roots lie in these areas.

#### Self-Assessment Questions

11. Why does the timing of the modern human out-of-Africa event affect the pattern of genetic variation we see among modern human groups?
12. How did phenotypic differences among different human populations arise?

## 23.5 CULTURE, LANGUAGE, AND CONSCIOUSNESS

The most remarkable outcome of the evolutionary process described in this chapter is the human brain. This brain allows us to do extraordinary things, such as play and appreciate music, write and read books, design and build skyscrapers, and invent and implant an artificial heart. But does this wonderful brain make us qualitatively different from other organisms? Does it in some way take us out of nature? Traditionally, the answer to these questions would have been a resounding “yes.” More recently, research into the capabilities of other species has questioned this conclusion. The human brain is certainly remarkable, but, in essence, what we can do is merely an extension of what other animals can do.

### Culture changes rapidly.

Culture is generally defined as a body of learned behavior that is socially transmitted among individuals and passed down from one generation to the next. Culture has permitted humans in part to transcend our biological limits. To take a simple example, clothing and ingeniously constructed shelters have enabled us to live in extraordinarily inhospitable parts of the planet, such as the Arctic ([Fig. 23.16](#)). The capacity to innovate coupled with the ability to transmit culture is the key to the success of humans.

Source: B&C Alexander/ArcticPhoto.

FIG. 23.16 The power of culture. Inventions (such as clothing) have allowed our species to expand its geographic range.

Culture, of course, changes over time. In many ways, this kind of cultural change is responsible for our species' extraordinary achievements. Genetic evolution is slow because it involves mutation followed by changes in allele frequencies that take place over many generations. Cultural change, in contrast, can occur much more rapidly. Twenty years ago, no one had heard of smartphones; today, millions of people own them. Or consider the speed at which a change in clothing style—a shift from flared to straight-leg jeans, for example—spreads through a population. Today's human population as a whole is genetically almost identical to the population when your grandparents were young, but the cultural changes that have occurred in the 50 years or so between your grandparents' youth and your own are astounding.

Despite this clear contrast between biological evolution and cultural change, we should not necessarily think of the two processes as

independent of each other. Sometimes cultural change drives biological evolution.

A good example of the interaction between cultural change and biological evolution is the evolution of lactose tolerance in populations for which domesticated animals became an important source of dairy product. Most humans around the world are lactose intolerant. Lactose, a sugar, is a major component of mammalian milk, including human breast milk. Humans have an enzyme, lactase, that breaks down lactose in the gut, but typically this enzyme is produced only in the first years of life, when we are breastfeeding. Once a child is weaned, lactase production is turned off. Lactase, however, is clearly a useful enzyme to have if there is a major dairy component to your diet.

Archaeological and genetic analyses indicate that cattle were domesticated probably three separate times in the past 10,000 years, in three separate places: in the Middle East, in East Africa, and in the Indus Valley. In at least two of these cases, subsequent human biological evolution has favored lactose tolerance, in the form of continued lactase production throughout life. Analysis of the gene region involved in switching lactase production on and off has revealed mutations in European lactose-tolerant people that are different from those in African lactose-tolerant people, implying independent, convergent evolution of this trait in the two populations. Furthermore, these changes appear to have evolved very recently, implying that they arose as a response to the domestication of cattle. This is an example of the interaction between cultural change and biological evolution. Biological evolution of continued lactase production has resulted from

the change in a cultural practice, namely cattle domestication.

## Is culture uniquely human?

Even nonprimates are known to be capable of learning from another member of their own species—culture is not uniquely human. Bird songs, for instance, may vary regionally because juveniles learn the song from local adults. In a famous case, illustrated in [Fig. 23.17a](#), small birds called blue tits (*Parus caeruleus*) in Britain learned from each other how to peck through the aluminum caps of milk bottles left on doorsteps by milkmen to reach the rich cream at the top of the milk. Presumably, one individual discovered accidentally how to peck through a milk bottle cap and others then imitated the action.

Sources: a. Colin F. Sargent; b. Dr. Alex Thornton, University of Exeter; c. FLPA/Peter Davey/AGE Fotostock.

**FIG. 23.17** Nonhuman culture. (a) English blue tits steal cream from a milk bottle on the doorstep. (b) Adult meerkats teach their young how to handle their prey. (c) Chimpanzees in different populations have devised different ways of using tools to hunt insects.

Nor is teaching, one way in which culture is transmitted, limited to humans. In teaching, one individual tailors the information available to another so as to facilitate learning. Teaching and imitation together make learning highly efficient. For example, adult meerkats teach young meerkats how to handle prey by giving them the opportunity to

interact with live prey ([Fig. 23.17b](#)).

The most sophisticated example of nonhuman culture involves chimpanzees. Detailed studies of several geographically isolated populations have revealed 39 culturally transmitted behaviors, such as ways of using tools to catch insects, which are specific to particular populations ([Fig. 23.17c](#)). West African chimpanzees in both Guinea and the Ivory Coast use tools to help them harvest the same species of army ant for food (and avoid the painful defensive bites of the ant), but each population has its own distinct way of doing this. Chimpanzees, then, are like humans in demonstrating regional variations in culture.

Despite the cultural achievements of other species, it is clear that culture in *Homo sapiens* is very far removed from anything seen in the natural world. Humans are amazingly adept at imitation, learning, and acquiring culture. Teaching, learning, and cultural transmission all benefit from another extraordinary human attribute, language.

## Is language uniquely human?

Language is a complex form of communication involving the transfer of information encoded in specific ways, such as speech, facial expressions, posture, and the like. Language is not unique to humans. The waggle dance of a worker bee on its return to the hive communicates information on the direction, distance, and nature of a food resource ([Chapter 43](#)). Vervet monkeys use warning vocalizations to specify the identity of a potential predator: they have one call for “leopard,” for example, and another for “snake.” But nonhuman animal languages are limited. Attempts to teach even our closest relatives,

chimpanzees, to communicate using sign language have met with only limited success ([Fig. 23.18](#)).

*Source: Laurentiu Garofeanu/Barcroft USA/BarcroftMedia/Getty Images.*

FIG. 23.18 Dr. Susan Savage Rumbaugh with Panbanisha, a female bonobo that learned to communicate using sign language. Chimpanzees and bonobos are able to learn and use sign language to express words and simple sentences.

Grammar provides a set of rules that allow us to combine words into a virtually infinite array of meanings. Noam Chomsky, father of modern linguistics, has pointed out that all human languages are basically similar from a grammatical viewpoint. Humans have what he has called a “universal grammar” that would lead a visiting linguist from another planet to conclude that all Earth’s languages are dialects of the same basic language. This universal grammar is “hard-wired” into the human brain in such a way that every human infant spontaneously strives to acquire language. The specific attributes of the language depend on the baby’s environment—a baby in France will learn French, and one in Japan will learn Japanese—but the basic process is similar in every case. Conversely, chimpanzees, and the entire natural world, lack the drive toward the acquisition of a grammatical language.

## Is consciousness uniquely human?

Descartes famously wrote, “Cogito, ergo sum”—“I think, therefore I am.” Can we legitimately rewrite his statement to declare, “Animals think, therefore they are”? With the growth of the animal rights movement, particularly in reference to the treatment of animals in factory farms, this question is of more than academic interest. We can cite many examples of animal thinking from a range of species, including, not surprisingly, chimpanzees and gorillas.

Perhaps even more remarkable are the examples that come from animal species that are not closely related to us. In experiments carried out by Alex Kacelnik in Oxford, England, a pair of New Caledonian crows was presented with two pieces of wire, one straight and the other

hooked, and offered a food reward that could be obtained only by using the hooked wire. One member of the pair, the male, disregarded the experiment and flew off with the hooked wire. The female, having discovered that she could not get the food reward with the straight wire, went to some considerable trouble to bend a hook into the straight wire. She succeeded in getting the food. It is difficult to deny that the crow thought about the problem and was able to solve it, perhaps in the same way that a human would. Definitions of consciousness are contested, but, as with language and culture, it seems clear that other species are capable of some form of conscious thought.

The evolutionary biologist Theodosius Dobzhansky once said, “All species are unique, but humans are uniquest.” Our “uniquest” status is not derived from having attributes absent in other species, but rather from the extent to which those attributes are developed in us. Human language, culture, and consciousness are extraordinary products of our extraordinary brains. Nevertheless, as Darwin taught us, we are fully a part of the natural world. Today, humans dominate the planet more comprehensively than any single species ever has before, meaning that Darwin’s lesson is crucially important: the future fate of the planet—home to us *and* millions of other species—is in our hands.

#### Self-Assessment Questions

13. What is an argument for the idea that culture, language, and consciousness are uniquely human?
14. What is an argument against the idea that culture, language, and consciousness are uniquely human?

---

## CORE CONCEPTS SUMMARY

**23.1 THE GREAT APES:** Anatomical, molecular, and fossil evidence shows that the human lineage branches off the great apes tree.

Anatomical features indicate that primates are a monophyletic group that includes prosimians, monkeys, and apes. The apes, in turn, include the lesser and great apes. [page 491](#)

The great apes include orangutans, gorillas, chimpanzees, and humans. [page 492](#)

Analysis of sequence differences between humans and our closest relatives, chimpanzees, indicate that the human lineage split from chimpanzees 5–7 million years ago. [page 493](#)

Lucy, an unusually complete specimen of *Australopithecus afarensis*, demonstrates that our human ancestors were bipedal by about 3.2 million years ago. [page 494](#)

Hominin fossils occur only in Africa until about 2 million years ago, when *Homo ergaster* migrated out of Africa to colonize the Old World. [page 496](#)

**23.2 HUMAN ORIGINS:** Phylogenetic analysis of mitochondrial DNA and the Y chromosome shows that the human species arose in Africa.

Studies of mitochondrial DNA (mtDNA) suggest that the common ancestor of all modern humans lived approximately 200,000 years ago, implying that modern humans (*Homo sapiens*) arose in Africa (the out-of-Africa hypothesis). [page 497](#)

The mtDNA out-of-Africa pattern is supported by Y chromosome analysis, which also shows a recent African origin of modern humans. [page 499](#)

Analysis of Neanderthal DNA from 30,000-year-old material indicates that, as the ancestors of non-African humans emigrated from Africa, they interbred with the Neanderthals. [page 500](#)

Our species originated in Africa and subsequently colonized the rest of the planet, starting about 60,000 years ago. [page 500](#)

**23.3 HUMAN TRAITS:** During the 5–7 million years since the most recent common ancestor of humans and chimpanzees, our lineage acquired a number of distinctive features.

The development of bipedalism involved a wholesale restructuring of anatomy. [page 501](#)

Neoteny is the process in which the timing of development is altered over the course of evolution so that a sexually mature organism retains the physical characteristics of the juvenile form; humans are neotenous, exhibiting several traits as adults that chimpanzees exhibit as juveniles. [page 502](#)

Many possible selective factors may explain the evolution of humans' large brain, including tool use, social living, and language. [page 502](#)

*FOXP2*, a gene involved in brain development, may be important in language, as mutations in *FOXP2* are implicated in speech pathologies. [page 503](#)

**23.4 HUMAN GENETIC VARIATION:** Human history has had an important impact on patterns of genetic variation in our species.

Because our ancestors left Africa very recently in evolutionary terms, there has been little time for genetic differences to accumulate among geographically separated populations. [page 504](#)

Humans have very little genetic variation, with only about 1 in every 1000 base pairs varying among individuals. [page 504](#)

Most of the variation among humans occurs within populations. As much as 85% of the total amount of genetic variation in humans can be found within a single population. Only about 7% of human genetic variation segregates between groups that are so-called races. [page 505](#)

Some differences among groups, such as skin color and resistance to malaria, have probably arisen by natural selection. [page 506](#)

Other differences among groups have probably arisen by sexual selection. [page 506](#)

**23.5 CULTURE, LANGUAGE, AND CONSCIOUSNESS:** Culture, language, and consciousness are developed to a remarkable degree in humans.

Cultural evolution and biological evolution may interact, as in the case of the evolution of lactose tolerance in regions where cattle were domesticated. [page 508](#)

Other animals possess simple versions of culture, language, and even consciousness, but the advances of our species in all three are

truly exceptional. [page 508](#)

## PART 2 FROM ORGANISMS TO THE ENVIRONMENT

## CASE 5

### The Human Microbiome

#### *Diversity Within*

*Clostridium difficile* doesn't grab many headlines, but perhaps it should. This bacterium is thought to be the most common cause of hospital-acquired infections in the United States. It sickens about half a million U.S. hospital patients each year, causing fevers, chills, diarrhea, and severe intestinal pain. It also adds more than \$1 billion annually to the nation's health-care costs. Altogether, the infection kills nearly 30,000 people every year, according to the Centers for Disease Control and Prevention.

Now a promising (if stomach-turning) new treatment is gaining traction: fecal transplants. The vast majority of *C. difficile* cases occur after patients have taken antibiotics for other infections. These drugs kill the beneficial bacteria normally found in a healthy gut, allowing *C. difficile* to proliferate. Recently, pioneering researchers have begun to replace the missing microbes by transplanting fecal material from healthy donors into patients sick with *C. difficile* infections. Some doctors have reported that the procedure alleviates symptoms in more than 80% of patients.

*No one has yet identified all of*

While transplanting  
fecal bacteria may not

*the many microbes living on and within our bodies, but recent estimates suggest that each of us contains at least as many bacterial cells as human cells.*

yet be mainstream medicine, there is no question that our gut, as well as our skin, mouth, nose, and urogenital tract, is home to a diversity of bacterial species. No

one has yet identified all of the many microbes living on and within our bodies, but recent estimates suggest that each of us contains at least as many bacterial cells as human cells. For the most part, the relationship between “us and them” is a type of symbiosis, in which both humans and bacteria benefit from the close association. Indeed, the human *microbiome*, as our assemblage of bacterial houseguests is known, affects human health in many important ways.

Some of the most mysterious, and most intriguing, members of that microbiome live in the gut. On the one hand, bacteria found in our intestines help us break down food and synthesize vitamins. On the other hand, abnormal communities of microbes in the gut have been linked to Crohn’s disease, colon cancer, and inflammatory bowel disease. The list of microbial residents in the human body grows longer each year.

Your own personal gut flora is a unique collection of species—even identical twins can have surprisingly different microbiomes. This variability has made it difficult for scientists to decipher exactly what role individual species play in health and in disease. The sheer

diversity of bacteria in the gut merely compounds the problem. One international team of scientists recently reported that each human gut contains at least 160 different bacterial species.

Despite these challenges, researchers have made strides toward understanding the unique bacterial communities within our intestinal tract. In 2011, scientists compared all the DNA sequences from gut microbes of people living in Europe, America, and Japan. They found that each individual fell into one of three enterotypes, or “gut types.” Most people had a bacterial mix dominated by organisms from the genus *Ruminococcus*. Others, however, had gut types dominated by the genus *Bacteroides* or the genus *Prevotella*. The three different gut compositions appear to produce different vitamins and may even make a person more, or less, susceptible to certain diseases. Continuing research shows that the boundaries between enterotypes may be fuzzier than originally thought, but understanding the variations in gut biota among human populations may in time lead to novel and focused treatments for diseases of the intestinal tract.

 Source: Mimi Haddon/Getty Images.

**The human microbiome.** Different groups of bacteria reside in or on each part of the body. When *Helicobacter pylori* is present in the stomach (*H. pylori* +), it can overwhelm other bacterial populations (*H. pylori* -), causing stomach ulcers and cancer.

Surprisingly, the researchers reported that enterotype was unrelated to gender, body mass index, or nationality. So what determines your gut type? A follow-up study suggested that enterotypes are associated with long-term dietary patterns. People who eat a diet high in animal protein and saturated fats are more likely to contain a gut community dominated by *Bacteroides*. In contrast, people who stick to a high-carbohydrate diet rich in plant-based nutrition are more likely to host an abundance of *Prevotella*.

The researchers don't know yet what a person's enterotype means for his or her health. But scientists are eager to explore the link between microbiome and physical well-being. Meanwhile, various researchers are exploring the microbiomes of other organisms—specifically, cows.

As it happens, there are good reasons to peer into a cow's gut. The cow's rumen (one of its four digestive chambers) contains microbes that break down the cellulose in plant material. Without them, cattle wouldn't be able to extract adequate nutrition from the grass on which they graze. Those microbes are the particular focus of scientists at the Department of Energy (DOE), who are interested in converting material containing cellulose, such as switchgrass, into biofuels.

As researchers look for more sustainable replacements for fossil fuels, many have pinned their hopes on biofuels. Unfortunately, the enzymes currently used commercially to break down cellulose aren't efficient or cost-effective enough to produce biofuels on an industrial scale. That's where the cows come in. When DOE scientists recently

analyzed the microbial genes present in the cow rumen, they discovered many genes for proteins that metabolize carbohydrates, at least 50 of which were previously unknown. The hope is that some of these newly discovered proteins will help break down cellulose in ways that will produce biofuels more efficiently and cheaply.

Mammals such as cows and humans are hardly the only organisms that have symbiotic relationships with bacteria. All living animals have their own microbiomes. Even tiny single-celled eukaryotes can harbor still-tinier bacterial guests.

Symbiotic bacteria provide a variety of benefits to their hosts. Consider the bobtail squid, *Euprymna scolopes*, which possesses a specialized organ to house bacteria. The bacteria residing there, *Vibrio fischeri*, are luminescent—that is, capable of generating light. The squid use their *Vibrio*-filled light organs like spotlights, projecting light downward to match light from the surface as a way to camouflage themselves from would-be predators below.

Source: Gary Bell/OceanwideImages.com.

The bobtail squid and its luminescent bacteria. This squid contains specialized organs that harbor light-emitting bacteria.

In many cases, animals and their bacterial symbionts are so

intimately connected that it's hard to separate one from the other. Many human gut bacteria are poorly studied because scientists haven't been able to grow them outside the body. In contrast, some other species have taken their intimate bacterial partnership a step further.

Aphids are small insects that feed on plant sap. They rely on the bacterium *Buchnera aphidicola* to synthesize certain amino acids for them that aren't available from their plant-based diet. The partnership between aphids and *Buchnera* dates back as far as 250 million to 150 million years ago. Over time, the organisms have become completely dependent on each other for survival. The *Buchnera* bacteria actually live inside the aphid's cells. In some ways, the bacteria resemble organelles rather than independent organisms. Intracellular symbionts may not be so unusual. In fact, mitochondria and chloroplasts—key organelles of eukaryotic cells—are thought to have originated from symbiotic bacteria. Over time, the progenitor bacteria became so intertwined with their host cells that they developed into an integral part of the cells themselves. Studying simple sap-sucking aphids, it turns out, may offer insights into the evolutionary history of all eukaryotic cells.

Clearly, there are many good reasons to learn more about our bacterial comrades. From evolution to energy to human health, our microbiomes hold great promise—and great mystery. We've evolved hand in hand with these bacteria for millions of years. Let's hope it takes less time to uncover their secrets.

## DELVING DEEPER INTO CASE 5

**For each of the Cases, we provide a set of questions to pique your curiosity. The questions cannot be answered directly from the Case itself, but instead introduce issues that will be addressed in chapters to come. We revisit this Case in [Chapters 24–25](#) on the pages indicated below.**

1. How do intestinal bacteria influence human health? See [page 541](#).
  2. What role did symbiosis play in the origin of chloroplasts? See [page 548](#).
  3. What role did symbiosis play in the origin of mitochondria? See [page 551](#).
  4. How did the eukaryotic cell originate? See [page 552](#).

## CHAPTER 24 Bacteria and Archaea

STEVE GSCHMEISSNER/SCIENCE PHOTO LIBRARY/Getty Images

---

## CORE CONCEPTS

**24.1 TWO PROKARYOTIC DOMAINS:** The two prokaryotic domains are Bacteria and Archaea.

**24.2 AN EXPANDED CARBON CYCLE:** Bacteria and Archaea cycle carbon in diverse ways.

**24.3 SULFUR AND NITROGEN CYCLES:** Bacteria and Archaea are critical to the biological cycling of sulfur and nitrogen.

**24.4 BACTERIAL DIVERSITY:** Genomic surveys of non-culturable bacteria reveal the extent of bacterial diversity.

**24.5 ARCHAEOAL DIVERSITY:** The diversity of Archaea has only recently been recognized.

**24.6 THE EVOLUTIONARY HISTORY OF PROKARYOTES:** The earliest forms of life on Earth were Bacteria and Archaea.

---

In [Chapters 7](#) and [8](#), we discussed the complementary metabolic processes of aerobic respiration and photosynthesis. Photosynthesis transforms CO<sub>2</sub> into organic molecules, and cellular respiration returns CO<sub>2</sub> to the environment. These two processes allow plants and animals to cycle carbon, which in turn is linked to their production and consumption of oxygen. But can carbon cycle through the deep waters of the Black Sea, within the black muds found beneath swamps and marshlands, or in other habitats where oxygen is limited or absent? Can biological communities even survive without oxygen? The answer, emphatically, is yes. Indeed, life existed on Earth for more than a billion years before oxygen-rich habitats first appeared on our planet.

The seemingly alien oxygen-poor environments on today's Earth are populated by organisms that neither produce nor consume oxygen, yet are able to cycle carbon. The organisms responsible for this expanded cycle share one fundamental feature: they have prokaryotic cell organization. Prokaryotes, which include bacteria and archaeons, lack a nucleus ([Chapter 5](#)). They inhabit the full range of environments present on Earth, including those rich in oxygen. Notably, however, their ability to live in habitats where plants and animals cannot suggests that some of these organisms have biological features quite unlike those of our familiar world.

The [carbon cycle](#) describes the path of carbon as it moves between organisms, the atmosphere, rocks, soil, and the ocean. We'll look at the carbon cycle again later in this chapter, but first we discuss [Bacteria](#) and [Archaea](#), the prokaryotic domains of microscopic organisms so critical to the cycling of carbon and other elements essential to life. We examine their diversity and consider how they have evolved through time.

# 24.1 TWO PROKARYOTIC DOMAINS

[Chapter 5](#) outlined the two distinct ways that cells are organized internally. Eukaryotic cells, which include the cells that make up our bodies, have a membrane-bounded nucleus and organelles that form separate compartments for distinct cell functions. Prokaryotic cells have a simpler organization. No membrane surrounds the cell's DNA, and there is little in the way of cell compartments. Prokaryotic cell organization is an ancestral character state for life as a whole—that is, this feature was present in the last common ancestor of all organisms alive today. Nevertheless, the group defined traditionally as the prokaryotes is paraphyletic, in that it excludes some descendants of the last common ancestor of all living organisms, namely eukaryotes ([Chapter 22](#)).

Bacteria and Archaea are the two domains characterized by prokaryotic cell structure. These organisms are present almost everywhere on Earth. What they lack in complexity of cell structure, these tiny cells more than make up for in their dazzling metabolic diversity. As will become clear over the course of this chapter, Bacteria and Archaea underpin the efficient operation of ecosystems on our planet.

## The bacterial cell is small but powerful.

Because of their small size and deceptively simple cell organization, bacteria were long dismissed as primitive organisms, distinguished

mostly by the eukaryotic features they lack: they have no membrane-bounded nuclei, no energy-producing organelles, no sex. This point of view turns out to be more than a little misleading. Bacteria are the diverse and remarkably successful products of nearly 4 billion years of evolution. Today, bacterial cells outnumber eukaryotic cells by several orders of magnitude. Even in your own body, bacteria equal or outnumber human cells.

**Fig. 24.1** illustrates the bacterial cell, which was briefly introduced in [Chapter 5](#). The cell's DNA is present in a single circular chromosome, in contrast to the multiple linear chromosomes characteristic of eukaryotic cells. Many bacteria carry additional DNA in the form of **plasmids**, small circles of DNA that replicate independently of the cell's circular chromosome. In general, plasmid DNA is not essential for the cell's survival, but it may contain genes that have adaptive value under specific environmental conditions. Because no nuclear membrane separates DNA from the surrounding cytoplasm, transcribed mRNA is immediately translated into proteins by ribosomes.

FIG. 24.1 A bacterial cell. The cells of Bacteria (and Archaea) do not have a membrane-bounded nucleus or other organelles.

Bacteria lack the membrane-bounded organelles found in eukaryotic cells. Instead, cell processes such as metabolism are carried out by proteins that float freely in the cytoplasm or are embedded in the plasma membrane. A few bacteria, notably the photosynthetic bacteria, contain internal membranes similar to those found in chloroplasts and mitochondria. The light-triggered reactions of photosynthetic bacteria take place in association with membranes distributed within the cytoplasm.

Structural support for bacteria is provided by a cell wall made of **peptidoglycan**, a complex polymer of sugars and amino acids. Some bacteria have thick walls made up of multiple peptidoglycan layers,

while others have thin walls surrounded by an outer layer of lipids. For many years, it was believed that bacteria lacked the cytoskeletal framework that organizes cytoplasm in eukaryotic cells. More recently, careful studies have shown that bacteria do possess an internal scaffolding of proteins that plays an important role in determining the shape, polarity, and other spatial properties of bacterial cells ([Chapter 10](#)).

## Diffusion limits cell size in bacteria.

Most bacterial cells are tiny: the smallest are only 200–300 nanometers (nm) in diameter, and relatively few are more than 1–2 micrometers ( $\mu\text{m}$ ) long. Why are bacteria so small? The answer has to do with diffusion, the random motion of molecules introduced in [Chapter 5](#). If you could watch the movement of any particular molecule in air or water, you would see that its motion is random, sometimes going in one direction and sometimes in another. On average, however, more molecules move from a region with a higher concentration of the molecule to a region with a lower concentration of the molecule than move in the opposite direction. Net movement stops only when the two regions achieve equal concentrations of the molecule, although diffusion continues. Photosynthetic bacteria gain the carbon dioxide they need by the diffusion of  $\text{CO}_2$  from the environment into the cell; similarly, respiring bacteria take in small organic molecules and oxygen by diffusion.

Diffusion explains why bacterial cells tend to be small. A small cell has more surface area in proportion to its volume, and the interior parts

of a small cell are closer to the surrounding environment than those of a larger cell. As a consequence, slowly diffusing molecules do not have to travel far to reach every part of a small cell's interior. The surface area of a spherical cell—the area available for taking up molecules from the environment—increases as the square of the radius. However, the cell's volume—the amount of cytoplasm that is supported by diffusion—increases as the cube of the radius. Therefore, as cell size increases, it becomes harder to supply the cell with the materials needed for growth. For this reason, most bacterial cells are tiny spheres, rods, spirals, or filaments—small enough for molecules to diffuse into the cell's interior ([Fig. 24.2](#)).

FIG. 24.2 Cell shape and size in Bacteria and Archaea.

A few exceptional bacteria exceed 100  $\mu\text{m}$  in length. The largest

known bacterium, *Thiomargarita namibiensis*, lives in oxygen-poor sediments off the coast of southwestern Africa. Its total volume is approximately 100 million times larger than that of *Escherichia coli* ([Fig. 24.3](#)). But, in one sense, *T. namibiensis* cheats: 98% of its volume is taken up by a large vacuole, so the metabolically active cytoplasm is restricted to a thin film around the cell's periphery. Thus, the distance through which nutrients move by diffusion is only a few micrometers, as in many other bacteria.

Source: Courtesy Heide Schulz-Vogt, Leibniz Institute for Baltic Sea Research, Department of Biological Oceanography.

FIG. 24.3 *Thiomargarita namibiensis*, the largest known bacterial cell. A vacuole takes up most of the volume of the cell, so the active cytoplasm is only a few micrometers thick. The small spheroidal granules consist of sulfur, formed by the metabolism of hydrogen sulfide in their environment.

Some bacteria are multicellular, forming simple filaments or sheets of cells. More unusual are myxobacteria, which aggregate to form multicellular reproductive structures that are composed of several distinct cell types (see [Fig. 24.2e](#)).

# Horizontal gene transfer promotes genetic diversity in bacteria.

Bacterial genomes are generally smaller than the genomes of eukaryotes, in part because bacteria lack the large stretches of noncoding DNA characteristic of eukaryotic chromosomes ([Chapter 13](#)). The streamlining of the bacterial genome confers certain benefits. For example, bacteria can reproduce rapidly when the nutrients required for their growth are available. Bacteria replicate their DNA from only one or a small number of initiation sites, so a smaller genome can be duplicated more quickly.

Bacteria do not undergo meiotic cell division and cell fusion. That is, they lack the sexual processes characteristic of eukaryotic organisms ([Chapters 11](#) and [40](#)). Despite this, bacterial populations display remarkable genetic diversity. For example, distinct populations of *Pseudomonas aeruginosa*, a common disease-causing organism, may differ in genome size by nearly a factor of 2 (3.7 million base pairs compared to 7.1 million base pairs), yet these strains are quite similar in function.

How does this variation arise? In eukaryotic organisms, genes generally pass from parent to offspring. Bacteria likewise inherit most of their genes from parental cells, but they can also obtain new genes from distant relatives by [horizontal gene transfer](#). This process is a major source of genetic diversity in bacteria.

How does DNA move from one bacterial cell into another independently of cell division? Some bacteria synthesize thin strands

of membrane-bound cytoplasm called pili ([Chapter 5](#)) that connect them to other cells ([Fig. 24.4a](#)). After joining to a second cell, the pilus contracts, drawing the two cells close together. A pore-like opening develops where the two cells are in close contact, providing a migration route for the direct cell-to-cell transfer of DNA. This process, called **conjugation**, commonly transfers plasmids from one cell to another, spreading novel genes throughout a population. Genes that confer resistance to antibiotics are a well-studied example of horizontal gene transfer by conjugation.

**a. DNA transfer by conjugation**

In conjugation, DNA (usually a plasmid) from a donor cell is transferred to an adjacent recipient cell. First, a pilus tethers the donor to the recipient and brings the cells together.

Once the cells are closely aligned, the DNA passes through a small opening formed between the cells.

**b. DNA transfer by transformation**

In transformation, DNA released into the environment by dead cells is taken up by a recipient cell.

**c. DNA transfer by transduction**

In transduction, DNA is transferred from a donor to a recipient cell by a virus.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company;  
Photo source: Dr. Linda M. Stannard, University of Cape Town/Science Source.

FIG. 24.4 Horizontal gene transfer in bacteria. DNA shown in red originates from the donor cell. DNA shown in blue is that of the recipient cell.

Genes can also be transferred from one cell to another without any direct bridge between cells. DNA released to the environment by cell breakdown can be taken up by other cells, in a process called **transformation** ([Fig. 24.4b](#)). Transformation was discovered when experiments showed that harmless strains of the bacteria causing pneumonia could be transformed into virulent strains by exposure to media containing dead cells of disease-causing strains ([Chapter 3](#)). Scientists reasoned that the transformation occurred because the living bacteria were taking up some substance from the dead cells. The “transforming substance” was later shown to be DNA. Today, biologists commonly use transformation in the laboratory to introduce genes into cells.

Viruses provide a third mechanism of horizontal gene transfer. Recall from [Chapter 18](#) that viruses that invade bacterial cells sometimes integrate their DNA into the host’s bacterial DNA. This viral DNA persists within the cells as they grow and divide. Before the virus leaves the cell to infect others, the viral DNA removes itself from the bacterial genome and is packaged in a protein capsule. The complete virus particle can then be released into the environment. This excision is not always precise, and sometimes genetic material from the bacterial host is incorporated into the virus. Viruses released from their host cell go on to infect others, bringing host-derived genes with them. Horizontal gene transfer by means of viruses is called **transduction** ([Fig. 24.4c](#)). It is common in nature and is also widely

used in the laboratory to introduce novel genes into bacteria for medical research.

Horizontal gene transfer allows bacterial cells to gain beneficial genes from organisms distributed throughout the bacterial domain and beyond. Indeed, bacteria everywhere are constantly reshaping their genomes. Bacteria, therefore, are not merely the poor cousins of eukaryotes, unable to generate genetic diversity by sexual recombination. Instead, bacteria have their own highly efficient mechanisms for adding and subtracting genes that permit them to evolve and adapt rapidly to local conditions. Perhaps the most widely discussed and worrisome manifestation of horizontal gene transfer is the rapid spread of antibiotic resistance among pathogenic bacteria ([Chapter 48](#)).

## Archaea form a second prokaryotic domain.

For many years, all prokaryotic cells were classified as bacteria. However, in 1977, George Fox and Carl Woese published a revolutionary hypothesis. Based on comparisons of RNA molecules from the small subunits of ribosomes (and later, comparisons of the genes for these RNAs), Fox and Woese argued that prokaryotic organisms actually fall into two distinct groups, as different from each other as either is from eukaryotes. If this is true, the tree of life must have three great branches: Bacteria, Eukarya, and the limb recognized by Fox and Woese, called Archaea ([Fig. 24.5](#)). Research since the late 1970s has confirmed this hypothesis. Like the cells of bacteria, archaeal cells are prokaryotic—they have no membrane-bounded

nucleus and their genes are arrayed along a single circular chromosome. Moreover, cell size in Archaea is also limited by diffusion, and genetic diversity is promoted by horizontal gene transfer, much as in Bacteria.

In detail, however, Archaea are quite distinctive ([Table 24.1](#)). Their membranes are made from lipids that differ from the fatty acids found in bacterial and eukaryotic membranes. Archaea also show a diversity of molecules in their cell walls, but none has the peptidoglycan characteristic of Bacteria or the cellulose or chitin found in most eukaryotic cell walls.

TABLE 24.1 Principal Differences among Archaea, Bacteria, and Eukarya

| CHARACTERISTIC | ARCHAEA | BACTERIA | EUKARYA |
|----------------|---------|----------|---------|
|                |         |          |         |

|                                                                           |     |     |     |
|---------------------------------------------------------------------------|-----|-----|-----|
| Cell contains a nucleus and other membrane-bound organelles               | No  | No  | Yes |
| DNA occurs in a circular form*                                            | Yes | Yes | No  |
| Ribosome size                                                             | 70s | 70s | 80s |
| Membrane lipids are ester-linked†                                         | No  | Yes | Yes |
| Photosynthesis with chlorophyll                                           | No  | Yes | Yes |
| Capable of growth at temperatures greater than 80°C                       | Yes | Yes | No  |
| Histone proteins present in cell                                          | Yes | No  | Yes |
| Operons present in DNA                                                    | Yes | Yes | No  |
| Introns present in most genes                                             | No  | No  | Yes |
| Capable of methanogenesis                                                 | Yes | No  | No  |
| Sensitive to the antibiotics chloramphenicol, kanamycin, and streptomycin | No  | Yes | No  |
| Capable of nitrogen fixation                                              | Yes | Yes | No  |
| Capable of chemoautotrophy                                                | Yes | Yes | No  |

\* Eukaryote DNA is linear.

† Archaea membrane lipids are ether-linked.

Archaea differ from Bacteria in another intriguing way. Transcription in archaeons employs RNA polymerase and ribosomes more similar to those of eukaryotes than to the components of bacteria ([Chapter 3](#)). Moreover, many of the antibiotics that target protein synthesis in bacteria are ineffective against archaeons, suggesting fundamental differences in translation as well.

Many of the microorganisms first identified as Archaea have

unusual physiological properties or inhabit extreme environments. For example, some archaeons live in acidic mine water at pH 1 (or less!). Others live in water salty enough to precipitate NaCl ([Fig. 24.6](#)), or in deep-sea hydrothermal vents where temperatures can exceed 100°C. We now know that many archaeons live under less extreme conditions in soils, lakes, and the sea. Indeed, they may be the most abundant organisms throughout much of the ocean.

*Source: David Wall/Alamy.*

FIG. 24.6 Archaeons in San Francisco Bay. These ponds are flooded and then evaporated to precipitate table salt. Salt-loving archaeons, conspicuous by their reddish purple pigment, thrive here.

#### Self-Assessment Questions

1. How are bacterial and archaeal cells similar, and how are they

different?

2. How do prokaryotic cells obtain nutrients, and how does this process put constraints on their size?
3. How does surface area and volume of a cell change with its size?
4. In eukaryotes, sexual reproduction is the main process that generates new gene combinations. How do bacteria generate new gene combinations in the absence of sexual reproduction?

## 24.2 AN EXPANDED CARBON CYCLE

In our discussion of metabolism in [Chapters 7](#) and [8](#), we emphasized oxidation–reduction (redox) chemistry. In redox reactions, a pair of molecules reacts, with one molecule becoming more oxidized and the other becoming more reduced. If we follow the transfer of electrons in a redox reaction, we see that the molecule that is reduced gains electrons, whereas the molecule that is oxidized loses electrons. Thus, reduction requires a source of electrons, or an electron donor, while oxidation requires a sink for electrons, or an electron acceptor.

In photosynthesis carried out by plants, algae, and cyanobacteria ([Chapter 8](#)), carbon dioxide ( $\text{CO}_2$ ) is reduced to form carbohydrates, and water is oxidized to oxygen gas ( $\text{O}_2$ ). Water is the electron donor needed to reduce  $\text{CO}_2$ , with this process generating  $\text{O}_2$  as a by-product. In respiration ([Chapter 7](#)), organic molecules are oxidized to  $\text{CO}_2$ , and  $\text{O}_2$  is reduced to water. In this case,  $\text{O}_2$  serves as the electron acceptor needed to oxidize organic molecules.

In all known photosynthetic eukaryotes, the photosynthetic reaction is **oxygenic**, or oxygen producing. There is a good reason for this behavior. Water occurs nearly everywhere and, in the oxygen-rich environments where most eukaryotic organisms thrive, no other molecule is available to donate electrons. Nonetheless, where oxygen is limited or absent, other electron donors such as hydrogen sulfide ( $\text{H}_2\text{S}$ ) are available for photosynthesis and are used by photosynthetic microorganisms. Similarly, essentially all respiration in eukaryotic

cells is **aerobic**, or oxygen using. Again, this makes good chemical sense because oxidation of carbohydrates using oxygen generates far more energy than can be obtained using other oxidants. Once again, where oxygen is absent, other electron acceptors can be used for respiration. The organisms that can use these alternative electron donors and electron acceptors are Bacteria and Archaea.

In oxygenic photosynthesis and aerobic respiration, carbon is cycled from the atmosphere to plants and animals, and back to the atmosphere, forming one circuit of the carbon cycle. Bacteria and Archaea can cycle carbon and harvest energy in unique ways, making them indispensable parts of nature (**Fig. 24.7**). Consequently, prokaryotic organisms are considered the real foundation of the carbon cycle, as they are capable of building and dismantling organic molecules throughout the full breadth of habitats on Earth.

FIG. 24.7 The biological carbon cycle. Microbes have complementary metabolisms that enable them to cycle carbon in ways other than those used by plants and animals.

## Many photosynthetic bacteria do not produce oxygen.

In saline bays along the west coast of Australia and many other low-lying tropical coastlines, carpets of a deep blue-green color cover tidal flats along restricted lagoons. High salinity and episodic exposure limit the colonization of these tidal flats by algae and animals ([Fig. 24.8](#)).

The carpets shown in [Fig. 24.8a](#) comprise densely packed communities of (mostly) bacteria and archaeons called microbial mats. These communities have a predictable structure based on the depths to which light and oxygen penetrate into the mat ([Figs. 24.8b](#) and [24.8c](#)).

FIG. 24.8 Microbial mats. Mats, like the example from (a) Western Australia, cover tidal flats and lagoons where salinity or other environmental factors inhibit animals and seaweeds. As shown by the example from (b) Cape Cod, microbial mats have sharp vertical gradients of light, oxygen, and other chemical compounds, so they support nearly all the energy metabolisms found in (c) the expanded carbon cycle.

In the upper layer, where both light and oxygen are present, the mat is dominated by cyanobacteria. These bacteria engage in photosynthesis just as plants and algae do, using water as an electron donor and releasing oxygen gas (the blue-green layer in [Fig. 24.8b](#)). It is the photosynthetic pigments in the cyanobacteria that impart the blue-green color to microbial mats. The cyanobacteria share this layer with heterotrophic bacteria, which get their carbon from preformed organic molecules. Both cyanobacteria and the heterotrophic bacteria respire aerobically, using  $O_2$  to oxidize organic molecules to  $CO_2$ . Thus, at the mat surface, prokaryotic microorganisms carry out a biological carbon cycle much like plants and animals do.

What happens beneath the mat surface is a different story. Note in [Fig. 24.8b](#) that a distinct purple layer lies beneath the blue-green mat surface. Light penetrates into this layer, but oxygen does not, because aerobic respiration rapidly consumes  $O_2$  within the mat ([Fig. 24.8c](#)). What kinds of organisms live where light is present and oxygen absent?

Like the cyanobacteria in the surface zone, many bacteria within the purple layer are photosynthetic, but they do not use water as an electron donor and so do not generate oxygen gas. Called [anoxygenic](#)

because they do not produce oxygen, these photosynthetic bacteria use electron donors such as hydrogen sulfide ( $\text{H}_2\text{S}$ ), hydrogen gas ( $\text{H}_2$ ), ferrous iron ( $\text{Fe}^{2+}$ ), and even the arsenic compound arsenite ( $\text{AsO}_3^{3-}$ ). Where  $\text{O}_2$  is present, these compounds oxidize quickly and so are not available for photosynthesis. Therefore, microorganisms that conduct anoxygenic photosynthesis are restricted to sunlit habitats where  $\text{O}_2$  is absent.

The purple color in the mat layer comes from **bacteriochlorophyll**, a light-harvesting pigment that is closely related to the chlorophyll found in plants, algae, and cyanobacteria (**Fig. 24.9a**). Because of its chemical structure, bacteriochlorophyll absorbs light most strongly at wavelengths different from those absorbed by the cyanobacteria above them in the mat (**Fig. 24.9b**).

a. Structures of light-absorbing pigments

The differences in structure (shown in red) between the bacteriochlorophyll used by anoxygenic photosynthetic bacteria and the chlorophyll used by cyanobacteria and chloroplasts in photosynthetic eukaryotes account for the differences in wavelengths absorbed by the two molecules.

b. Absorption spectra

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 24.9 Bacteriochlorophyll *a* and chlorophyll *a*. Note that bacteria absorb wavelengths of light that are outside the visible spectrum.

Anoxygenic photosynthesis differs from oxygenic photosynthesis in another important way: it employs only a single photosystem. Recall from [Chapter 8](#) that a photosystem is a protein–pigment complex that absorbs light, which then powers photosynthesis. A single photosystem

cannot capture enough energy to oxidize water and then use those electrons to reduce  $\text{CO}_2$ . Therefore, oxygenic photosynthesis relies on two photosystems that operate in tandem. With only a single photosystem, bacteria that carry out anoxygenic photosynthesis use electron donors that donate their electrons more easily than water.

## Many bacteria respire without oxygen.

Light, but not oxygen, penetrates into the purple layer in [Fig. 24.8b](#), but neither light nor oxygen reaches the black layer deep within the microbial mat. Even so, both of these layers are inhabited by a diverse array of heterotrophic Bacteria and Archaea that metabolize the organic molecules originally synthesized by photosynthetic bacteria higher in the mat community.

Because no oxygen is present in these layers, the organisms found there must use other molecules as electron acceptors in cellular respiration, including oxidized forms of nitrogen ( $\text{NO}_3^-$ ), sulfur ( $\text{SO}_4^{2-}$ ), manganese ( $\text{Mn}^{4+}$ ), iron ( $\text{Fe}^{3+}$ ), and even arsenic ( $\text{AsO}_4^{3-}$ ). Such microorganisms thrive in many environments where oxygen is lacking.

Still other types of heterotrophs live in deeper layers of microbial mats. These heterotrophs may rely on [fermentation](#) rather than cellular respiration as a way of extracting energy from organic molecules. Whereas cellular respiration entails the full oxidation of carbon compounds to  $\text{CO}_2$ , fermentation involves the partial oxidation of carbon compounds to molecules that are less oxidized than  $\text{CO}_2$  ([Chapter 7](#)). On the one hand, fermentation has an advantage over

cellular respiration in that it does not require an external electron acceptor, such as  $O_2$ . On the other hand, fermentation yields only a modest amount of energy.

Fermentation plays an important role in oxygen-poor environments that are rich in organic matter, such as landfills and the digestive tracts of animals. In these settings, the breakdown of organic molecules typically requires more than one organism, each of which is able to metabolize a different intermediate. These cooperating groups of fermenters can break down substances that could not be metabolized by any one organism alone. In essence, groups of fermenters form an ecological solution to the metabolically difficult problem of gaining energy from complex organic molecules. Fermentation is widespread in Bacteria and Archaea, but is of only minor importance in most organisms belonging to Eukarya. The exception is yeasts, which thrive in the sugar-rich environment of rotting fruit, as well as in breweries throughout the world.

In summary, where  $O_2$  is present, many different kinds of organisms participate in the carbon cycle. Photosynthetic plants, algae, and cyanobacteria all transform  $CO_2$  into organic molecules, and animals, fungi, single-celled eukaryotes, bacteria, and archaeons return  $CO_2$  to the environment through aerobic respiration. However, only prokaryotic heterotrophs can complete the recycling of organic carbon in oxygen-poor environments. Thus, in carrying out anaerobic respiration or a diversity of fermentation reactions, prokaryotes play a major role in the carbon cycle.

## Photoheterotrophs obtain energy from light but obtain carbon from preformed organic molecules.

In [Chapter 6](#), we saw that organisms have two sources of energy: the sun (phototrophs) and chemical compounds (chemotrophs). Organisms also have two sources of the carbon needed for growth and other functions: inorganic molecules like  $\text{CO}_2$  (autotrophs) and organic molecules like glucose (heterotrophs). Thus, organisms can acquire the energy and carbon they need in four different ways (see [Fig. 6.1](#)).

Up to this point, we have considered only two of these ways. Plants, algae, and cyanobacteria are photoautotrophs, gaining energy from sunlight and carbon from  $\text{CO}_2$ , whereas animals, fungi, and many prokaryotes are chemoheterotrophs, gaining both energy and carbon from organic molecules taken up from the environment. Among the Bacteria and Archaea, additional mechanisms of metabolism are possible. Some use the energy from sunlight to make adenosine triphosphate (ATP), just as plants do, but rather than reducing  $\text{CO}_2$  to make their own organic molecules, they rely on organic molecules obtained from the environment as their source of carbon. These organisms are [photoheterotrophs](#).

Photoheterotrophy can be advantageous in environments that are rich in dissolved organic compounds. In particular, organisms can use all of their absorbed light energy to make ATP while directing all absorbed organic molecules toward growth and reproduction.

Photoheterotrophic bacteria have a single photosystem, so they can live

where oxygen is limited or absent. The purple layer of a microbial mat very likely contains heliobacteria or green nonsulfur bacteria, as both are photoheterotrophs that take advantage of the large amounts of organic matter generated by photoautotrophs in the mat.

## Chemoautotrophy is a uniquely prokaryotic metabolism.

On the deep seafloor, animals are relatively uncommon, their abundance limited by the slow descent of organic matter from the ocean's surface. Perhaps surprisingly, then, animal populations can be remarkably dense around hydrothermal vents ([Fig. 24.10](#)), places where hot water from the Earth's interior is expelled into the overlying sea. Why are animals so abundant here?

*Source: Science Source/Getty Images.*

FIG. 24.10 Deep-sea hydrothermal vents. Chemoautotrophs fuel the carbon cycle in these environments.

Many of the animals found around deep-sea hydrothermal vents subsist on a thriving community of microorganisms. These microorganisms gain carbon by reducing  $\text{CO}_2$  to form carbohydrates. However, they obtain the energy to fuel this process not from sunlight, but rather from chemical reactions. Hence, these microorganisms are **chemoautotrophs**. They oxidize molecules and ions such as  $\text{H}_2$ ,  $\text{H}_2\text{S}$ , and  $\text{Fe}^{2+}$  to generate the ATP and reducing power required to incorporate  $\text{CO}_2$  into organic molecules. In chemoautotrophic metabolism, the electron acceptor is most commonly  $\text{O}_2$  or nitrate ( $\text{NO}_3^-$ ). Thus, chemoautotrophy requires access to both oxidized ( $\text{O}_2$  and nitrate) and reduced ( $\text{H}_2$ ,  $\text{H}_2\text{S}$ , and  $\text{Fe}^{2+}$ ) substances.

Oxidized and reduced molecules react readily with each other, so they are rarely present in the same environment. For this reason, chemoautotrophs tend to live along the interface between an environment where oxygen is present and one in which oxygen is absent. Notably, chemoautotrophic prokaryotes thrive along hydrothermal vents, where reduced gases from Earth's interior meet oxygen-rich seawater.

#### Self-Assessment Questions

5. How can photosynthesis occur without the production of oxygen, and how can respiration occur without requiring oxygen?
6. How do photoautotrophs such as cyanobacteria differ from

photoheterotrophs such as heliobacteria?

7. How did the biological carbon cycle work on the early Earth, where oxygen gas was essentially absent from the atmosphere and oceans?

## 24.3 SULFUR AND NITROGEN CYCLES

Let's think further about prokaryotic metabolism. We saw that some photosynthetic and chemoautotrophic bacteria oxidize reduced sulfur compounds like  $\text{H}_2\text{S}$  to sulfate ( $\text{SO}_4^{2-}$ ), whereas some heterotrophic bacteria reduce sulfate to  $\text{H}_2\text{S}$ . These reverse chemical transformations may remind you of the carbon cycle outlined in [Chapters 7](#) and [8](#), in which plants generate oxygen and animals consume it. As Bacteria and Archaea have already shown us, mechanisms of metabolism at work where oxygen is absent can also complete the carbon cycle, taking in and releasing  $\text{CO}_2$ . They do so by coupling the cycling of carbon to the cycling of other elements—in this case, sulfur. Once again, we see complementary metabolic pathways. The expanded carbon cycle of Bacteria and Archaea promotes the cycling of sulfur, nitrogen, and other biologically important elements.

### Bacteria and archaeons dominate Earth's sulfur cycle.

The human body is mostly carbon, oxygen, and hydrogen, but we also contain approximately 0.2% sulfur by weight. Sulfur is a component of the amino acids cysteine and methionine and, therefore, is present in many proteins ([Chapter 2](#)). Sulfur is also present in the iron–sulfur clusters that are key components of enzymes fundamental to electron transfer ([Chapter 6](#)) and in some vitamins. Where do we get the sulfur we need? From the food we eat. In particular, protein in steak or fish provides an especially rich source of sulfur. Where do cows and fish

get the sulfur they need? Like humans, from the food they eat. Food chains don't go on forever, so somewhere in the system, some organisms must take up inorganic sulfur from the environment.

**Primary producers**, the organisms that reduce  $\text{CO}_2$  to form carbohydrates, fulfill this role.

Plants are the dominant primary producers on land. In the process called **assimilation**, plants take up sulfate ( $\text{SO}_4^{2-}$ ) ions from the soil and reduce them within their cells to hydrogen sulfide ( $\text{H}_2\text{S}$ ) that can be incorporated into cysteine and other biomolecules (**Fig. 24.11**).

Algae and photosynthetic bacteria do much the same thing in lakes, rivers, and oceans. Why don't primary producers take up  $\text{H}_2\text{S}$  directly? There are two answers to this question. First,  $\text{H}_2\text{S}$  is rapidly oxidized in the presence of oxygen, so it does not occur in environments where oxygenic photosynthesis is common. Second,  $\text{H}_2\text{S}$  is toxic to most eukaryotic organisms, so plants and algae do not thrive where it is abundant. (The  $\text{H}_2\text{S}$  produced within eukaryotic cells has a short lifetime and is restricted to intracellular sites distant from those that are vulnerable to its toxic effects.)

FIG. 24.11 The sulfur cycle. Plants take up sulfur in the form of sulfate ions for incorporation into proteins and other compounds, and fungi release sulfur during decomposition. However, the major role in cycling sulfur through the biosphere is played by microbes that oxidize or reduce sulfur compounds to gain energy or carbon.

We've now seen half the sulfur cycle, the conversion of sulfate to  $\text{H}_2\text{S}$  within cells. But how did sulfate molecules get into the soil in the first place? After cells die, fungi and bacteria decompose the cells, returning their carbon, sulfur, and other compounds to the environment. Reduced sulfur compounds released from decomposing cells are oxidized to sulfate by bacteria and archaeons, completing the cycle. These microbes are either chemoautotrophs that obtain energy by oxidizing  $\text{H}_2\text{S}$  or photosynthesizers that use  $\text{H}_2\text{S}$  as the electron donor. Some of this sulfur is assimilated by primary producers, but where oxygen is not available, much of it is consumed by heterotrophic bacteria. These bacteria use sulfate rather than oxygen as the final electron acceptor in respiration and reduce it to  $\text{H}_2\text{S}$ . In fact, most of the sulfur cycled biologically is used to drive energy metabolism in

oxygen-poor environments, rather than to build proteins.

Note that eukaryotes use neither  $\text{H}_2\text{S}$  for photo- (or chemo-) synthesis nor sulfate in respiration. Thus, the biological sulfur cycle is completed by bacteria and archaeons alone.

## The nitrogen cycle is also driven by bacteria and archaeons.

The model provided by the sulfur cycle can be extended to other biologically important elements. Nitrogen is the fourth most abundant element in the human body, contributing 3% by weight as a component of proteins, nucleic acids, and other compounds. As is true of sulfur, primary producers incorporate inorganic forms of nitrogen into biomolecules, and we get the nitrogen we need from our food. As we'll see, however, there is a twist.

Let's examine the biological nitrogen cycle ([Fig. 24.12](#)). Carbon is a minor component of the atmosphere and sulfur only a trace constituent; the air we breathe consists mostly (78%) of nitrogen gas ( $\text{N}_2$ ). Indeed, most of the nitrogen at Earth's surface resides in the atmosphere. Although nitrogen is plentiful, the nitrogen available to primary producers in many environments is limited. The reason is that neither plants nor algae can make use of nitrogen gas. Indeed, only certain bacteria and archaeons can reduce  $\text{N}_2$  to ammonia ( $\text{NH}_3$ ), a form of nitrogen that can be incorporated into biomolecules.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 24.12 The nitrogen cycle. Unique bacterial and archaeal metabolisms include nitrogen fixation, nitrification and denitrification, and anammox.

The process of converting  $N_2$  into a biologically useful form such as ammonia is called **nitrogen fixation**, and it is one of the most important reactions ever evolved. Farmers plant soybeans to regenerate nitrogen nutrients in soils, but it is not the soybean that fixes nitrogen. Instead, nodules on soybean roots harbor nitrogen-fixing bacteria ([Fig. 24.13](#)). Plants like soybean have entered into an intimate partnership with nitrogen-fixing bacteria to obtain the biologically useful forms of nitrogen needed for growth ([Chapter 27](#)).

Source: Scimat/Getty Images.

FIG. 24.13 Roots of a soybean plant. The nodules contain bacteria capable of reducing nitrogen gas to ammonia.

The nitrogen cycle, then, begins with nitrogen fixation, and it continues as further chemical transformations are carried out by many additional metabolisms, most of them confined to bacteria and archaeons. The nitrogen taken up by plants and animals is released in the form of ammonia by the decomposition of dead cells. Ammonia can be taken up by primary producers, but more commonly it is oxidized to nitrate ( $\text{NO}_3^-$ ) by chemoautotrophic bacteria, a process called **nitrification** (see [Fig. 24.12](#)). Because this process works efficiently in both soil and water, nitrate is the most common form of nitrogen available to life in both environments. Most primary producers can assimilate nitrate as well as ammonia.

Anaerobic respiration completes the nitrogen cycle by returning  $\text{N}_2$  to the atmosphere. Some bacteria can use nitrate as an electron acceptor in respiration, a process known as **denitrification** (see [Fig.](#)

[24.12](#)). Accepting an electron sets off the transformation of nitrate into  $\text{N}_2$ . Because denitrification is so efficient at returning nitrogen to the atmosphere as nitrogen gas, nitrogen fixation must continually make nitrogen available for organisms. Without nitrogen fixation, the nitrogen cycle would slowly wind down, and the productivity of Earth's biota—that is, of all its organisms—would wind down with it. This is why nitrogen fixation is such an important process.

Until the 1990s, the nitrogen cycle was described—completely, it was thought—in terms of the metabolic reactions just discussed. Then, a new and unexpected form of nitrogen metabolism was discovered in the oceans. A number of prokaryotic microorganisms function as chemoautotrophs by reacting ammonium ion ( $\text{NH}_4^+$ ) with nitrite ( $\text{NO}_2^-$ ) to gain energy. The reaction is shown here:

Note that this is a redox reaction, like other reactions of energy metabolism. In this case, the ammonium ion is oxidized to nitrogen gas, and nitrite is reduced to nitrogen gas. Water is produced as a by-product. This reaction, called [anammox](#) (anaerobic ammonia oxidation), provides only a small amount of energy, but it supports many bacteria and archaeons in oxygen-depleted parts of the ocean. In doing so, it provides a second major route by which fixed nitrogen returns to the atmosphere as  $\text{N}_2$  (see [Fig. 24.12](#)).

The biological nitrogen cycle, then, begins and ends with prokaryotic metabolisms. Bacteria and archaeons fix  $\text{N}_2$  into a biologically available form, and nitrifying bacteria oxidize ammonia to

nitrate. Other prokaryotes gain energy from denitrification and anammox, returning  $N_2$  to the air. Unlike the carbon and sulfur cycles, the nitrogen cycle does not rely at any point on elements stored as minerals in rocks and sediments. Most of Earth's nitrogen was released to the atmosphere as gas early in our planet's history, and today movement into sediments and out of volcanoes contributes relatively little to the cycle. Humans, however, contribute in important ways, most notably through the industrial synthesis of nitrate fertilizer ([Chapter 48](#)).

#### Self-Assessment Questions

8. What are the roles of bacteria and archaeons in the sulfur and nitrogen cycles?
9. How would the nitrogen cycle operate in the absence of bacteria and archaeons?

## 24.4 BACTERIAL DIVERSITY

Traditionally, bacterial taxonomy was a laborious process.

Microbiologists grew bacteria in beakers or on petri dishes, carefully separating and enriching individual populations until only one type of bacterium—that is, a pure culture—was present. Species were identified on the basis of details of cell structure and division observed under the microscope, and metabolic capabilities were established through experiments and reactions to chemical stains or antibiotics. By the 1980s, a few thousand species had been described.

With the sequencing technologies now available, bacterial species are increasingly being characterized by their DNA sequences, especially the genes for the small subunit of ribosomal RNA (rRNA). A novel application of sequencing technology paved the way for modern studies of bacterial diversity and ecology. Microbiologists reasoned that the same procedures used to extract, amplify, and sequence genes from pure cultures in the lab could be used to study bacteria in nature. That is, they could extract and read gene sequences directly from soil or seawater, thereby revealing the diversity of the microbial communities in these environments.

The results were stunning. Most bacteria in nature—perhaps 99% or more—are species that have not been cultured in the lab. Indeed, species that have been studied in pure cultures are commonly only minor components of natural communities. To give just one illustration, a bacterium called SAR11 was originally identified on the basis of gene sequences amplified from seawater. SAR11 caught the attention of microbiologists because it makes up approximately one-

third of all sequences identified in samples from the surface ocean. How could we be ignorant of a bacterium that must be among the most abundant organisms on Earth? The answer is simple: no one had cultured it. Recently, SAR11 has been cultured. Formally described as *Pelagibacter ubique* (*ubique* is Latin for “everywhere”), this bacterium is now known to be one of several closely related heterotrophs that play an important role in recycling organic molecules dissolved in the sea.

More recently, biologists have figured out how to sequence whole genomes from environmental samples. Using this sequence information, microbiologists have begun to match uncultured populations with specific metabolisms. We no longer need be content just to know from molecular sequences what is living in a given environment. Instead, we can now begin to understand what the different microorganisms are doing there. For this reason, another revolution in our understanding of the microbial world has begun ([Fig. 24.14](#)).

#### HOW DO WE KNOW?

### FIG. 24.14

## How many kinds of bacterium live in the oceans?

#### BACKGROUND

The oceans are full of bacteria. By some estimates, the sea harbors more than  $10^{29}$  bacterial cells. How diverse are these bacterial communities?

#### METHOD 1

Different types of bacterium can be recognized by the unique nucleotide sequences of their genes. In fact, individual types of bacterium can be identified on the basis of the nucleotide sequence in a relatively small region of the gene for the small subunit of ribosomal RNA (rRNA). This molecular “barcode” can be sequenced quickly and accurately for samples of DNA drawn from the environment.

Using this strategy, American biologist Mitchell Sogin and colleagues associated with the International Census of Marine Life obtained samples of seawater and seafloor sediment from deep-ocean environments. In the laboratory, the genes that code for rRNA were amplified by means of the polymerase chain reaction (PCR, a technique that allows a targeted region of a DNA molecule to be replicated into many copies), separated by gel electrophoresis, and sequenced. These rRNA sequences provide a library of tags that document bacterial diversity.

## METHOD 2

In another set of experiments, scientists collected samples of seawater from the Sargasso Sea. From these samples, they amplified whole genomes—more than 1 billion nucleotides’ worth. They used small-subunit rRNA and other genes to characterize species richness, and a large assortment of additional sequence data to understand genetic and physiological diversity.

## RESULTS

Both surveys found that the bacterial diversity of marine environments is much higher than had been thought. The barcode survey (method 1) found as many as 20,000 distinct types of bacteria in a single liter of seawater (bottom graph). From these results, it is estimated that as many as 5–10 million different microbes may live in the world’s oceans. Some of these bacteria are abundant and widespread, but most are rare. The genomic survey (method 2) of the Sargasso Sea found more than 1800 distinct

bacteria in sea-surface samples (top graph). Remarkably, this survey identified more than 1.2 million previously unknown genes within these genomes.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

Relative abundance of different bacterial groups in samples from the Sargasso Sea. Each bar shows the percentage of all small-subunit rRNA sequences represented by a unique small-subunit rRNA sequence. Note the abundance of SAR11, which has only recently been characterized.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

Computer-aided comparison of sequences from the world's oceans shows that approximately 75% of all sequences collected are similar to other sequences in the library of sequence tags. However, 25% are distinctive, forming a rare but enormously diverse pool of bacterial types.

## CONCLUSION

The bacterial diversity of the oceans is huge and still largely unexplored. Both barcode and genomic surveys are continuing, and promise a more nearly complete accounting of marine diversity. Together, these surveys will help us understand how marine bacteria function and how they sort into communities.

# Bacterial phylogeny is a work in progress.

In [Chapter 22](#), we introduced molecular phylogenies, which are

constructed by comparing gene or protein sequences. Through such comparisons, we can draw conclusions about evolutionary relatedness among populations in nature. Gene sequencing made it possible to test traditional bacterial groupings based on form and physiology. Some traditionally defined groups—for example, the cyanobacteria—passed the test and stand today as well-defined bacterial groups. Many others did not.

Molecular sequence comparisons bring enormous opportunities to the study of prokaryotic diversity and evolution, but they introduce new problems as well. One set of problems arises because major groups of Bacteria and Archaea separated from one another billions of years ago. Inherited sequence similarities can be masked by continuing molecular evolution within groups. That is, specific nucleotides in gene sequences may change not once, but multiple times throughout a long evolutionary history, erasing molecular features that were once the same because of inheritance from a common ancestor. Also, in some groups rates of sequence evolution appear to be higher than in others. As a result, these groups have especially divergent sequences and, in turn, may mistakenly be placed toward the bottom of their phylogenetic trees ([Chapter 22](#)).

Another problem arises because of horizontal gene transfer. Phylogenies may falsely group distantly related bacteria because they contain genes passed on by conjugation, transformation, or transduction. Statistical analyses of complete bacterial genomes suggest that at least 85% of all genes in bacterial genomes have been transferred horizontally at least once. Such apparently rampant gene

exchange might well doom attempts to build a bacterial tree of life. As an alternative, some biologists argue that bacterial evolution is more properly depicted as a complex bush with many connecting branches (**Fig. 24.15**).

**FIG. 24.15 Bacterial and archaeal phylogeny.** Some scientists argue that the evolution of prokaryotes should be viewed not as a tree, but rather as a series of branches that diverge and then come back together. This arrangement of branches represents genes that diverge from one another but then come to reside together in new organisms through horizontal gene transfer. *Data from W. F. Doolittle, 2000, "Uprooting the Tree of Life," Scientific American 282:90–95.*

Other microbiologists are more optimistic. Small-subunit rRNA

genes, for example, show little evidence of horizontal transfer, suggesting that they might faithfully record the evolutionary history of the organisms in which they occur. Nonetheless, we need to be cautious when using bacterial trees to study the evolution of specific metabolic or physiological characteristics. Nitrogen fixation, photosystems, drug tolerance—such features depend on genes known to jump from branch to branch on the tree.

To date, molecular signatures have been extremely useful in identifying major groups of bacteria, but their contributions are less clear in establishing branching order among these groups. Nearly 100 major groups of bacteria (each one very roughly equivalent to a eukaryotic phylum) have been recognized. Nearly half of these groups cannot now be cultured, but rather have been identified solely through the cloning of genes from environmental samples. To support our discussion of bacterial diversity, we present a phylogeny based on comparisons of whole genomes in [Fig. 24.16](#). As you examine this figure, remember that microbiologists continue to debate branching order on the bacterial tree. Remarkably, the large branch labeled Candidate Phyla consists of bacteria that were unknown before 2015. Few of these microbes have been cultured, but their genomes suggest that most cannot synthesize nucleotides or amino acids; thus, they may live in symbiotic association with other organisms. We still have a lot to learn about bacterial diversity on land and in the sea.

FIG. 24.16 Evolutionary relationships among bacteria, inferred from data from 1000 complete genomes. Photosynthetic groups are shown in green (the Acidobacteria have one known photoheterotrophic member). Other groups discussed in the text are shown in red. The branch labeled “Candidate phyla” has only recently been discovered. Data from A. Hug et al., 2016, *Nature Microbiology* 1:16048; Mukherjee et al., 2017, *Nature Biotechnology* 35:676–683.

## What, if anything, is a bacterial species?

What do we mean when we talk about bacterial species? As we saw in

[Chapter 21](#), Ernst Mayr defined species as “groups of interbreeding natural populations that are reproductively isolated from other such groups.” This widely accepted definition is called the biological species concept, but a moment’s reflection will show that it can’t be applied to the most abundant organisms on Earth—Bacteria and Archaea. Organisms in these domains cannot interbreed because there is no sexual reproduction. How, then, do we think about species in the prokaryotic domains?

Some microbiologists argue that we should abandon the concept of species when talking about bacteria, especially since distantly related bacteria can exchange genes. Nonetheless, nature is full of microbial populations with well-defined features of form and function.

In the age of molecular sequence comparisons, bacterial species have sometimes been defined as populations whose small-subunit rRNA sequences are more than 97% identical. It would be useful, however, to conceive of bacterial species in terms of a functional process, much as Ernst Mayr did for eukaryotic organisms. In plants, animals, and single-celled eukaryotes, interbreeding ensures that populations share the same pool of genes. That is, interbreeding provides a counterforce to the mutations and selection pressures that promote divergence.

A similar process exists in bacteria. In early research on the population genetics of bacteria, biologists observed that genetic diversity in laboratory cultures gradually increases through time and then rapidly decreases with the emergence of a successful variant that

outcompetes the rest. This kind of episodic loss of diversity is called **periodic selection**. Some biologists argue that the periodic selection process provides a means of recognizing bacterial species: populations selected during the same episode of periodic selection belong to a single species. This is a useful way to define bacterial species, but other definitions are possible, and as yet there is no consensus among microbiologists.

## Proteobacteria are the most diverse bacteria.

Given the immense and still unfolding diversity of bacteria, we cannot hope to discuss all major groups here. Instead, we introduce a few of the most diverse, ecologically interesting, or medically important groups of bacteria.

**Proteobacteria** are far and away the most diverse of all bacterial groups ([Fig. 24.16](#)). Defined largely by similarities in their rRNA sequences, Proteobacteria include many of the organisms that populate our expanded carbon cycle and other biogeochemical cycles. For example, they include anoxygenic photosynthetic bacteria and chemoautotrophs that oxidize  $\text{NH}_3$ ,  $\text{H}_2\text{S}$ , and  $\text{Fe}^{2+}$ , as well as bacteria able to respire using  $\text{SO}_4^{2-}$ ,  $\text{NO}_3^-$ , or  $\text{Fe}^{3+}$ .

Many Proteobacteria have evolved intimate ecological relationships with eukaryotic organisms. Some of these are mutually beneficial, such as the association between soybeans and nitrogen-fixing bacteria in root nodules. Other Proteobacteria are our worst pathogens: the *Rickettsia* bacteria that cause typhus and spotted fever, the *Vibrio*

species that trigger cholera, the *Salmonella* bacteria responsible for typhoid fever and food poisoning, and the *Pseudomonas aeruginosa* strains that infect burn victims and others whose resistance to infection is reduced. *Escherichia coli*, famous as a laboratory model organism (see [Fig. 24.4b](#)), is usually a harmless presence in our intestinal tract, but pathogenic strains can cause serious diarrhea and even death.

## The gram-positive bacteria include organisms that cause and cure disease.

In 1884, the Danish scientist Hans Christian Gram developed a diagnostic dye that, after washing, is retained by bacteria with thick peptidoglycan walls, but not by those with thin walls. Bacteria that retain the dye are now called [gram-positive bacteria](#). Molecular sequence comparisons confirm that most gram-positive bacteria form a well-defined branch of the bacterial tree ([Fig. 24.16](#)). One species in this group, *Bacillus subtilis*, is the focus of many studies exploring basic molecular function in bacteria. All of us harbor *Streptococcus* species in our mouths, and many of us have suffered from strep throat, produced by streptococcal pathogens. More serious infections, including some forms of meningitis, are also associated with streptococci. *Staphylococcus* bacteria are commonly found on human skin, but only occasionally do we suffer from maladies such as staph infection, toxic shock syndrome, or food poisoning induced by these bacteria.

In contrast to these pathogens, gram-positive bacteria called streptomycetes have a remarkable property that has proved invaluable to medicine. More than half of the species in this group secrete

compounds that kill other bacteria and fungi. Streptomycetes have provided us with tetracycline, streptomycin, erythromycin, and many other antibiotics that combat infectious disease.

## Photosynthesis is widely distributed on the bacterial tree.

Molecular studies confirm that all bacteria capable of oxygenic photosynthesis form a single branch of the bacterial tree, known as the [cyanobacteria](#). Cyanobacteria can be found in environments that range from deserts to the open ocean. Their diverse species include unicellular rods and spheroidal cells, as well as multicellular balls and filaments ([Fig. 24.17](#)). Some filamentous cyanobacteria can even form several different cell types, including specialized cells for nitrogen fixation and resting cells that provide protection when the local environment does not favor growth.

**a.** *Aphanothece*, small single cells

**b.** *Chroococcus*, larger cells bound into a colony by a common extracellular envelope made of polysaccharides

**c.** *Oscillatoria*, filaments with no cell differentiation

**d.** *Anabaena*, strings of undifferentiated cells at either end of the filament, flanking two elongated resting cells, and in the middle, a heterocyst specialized for nitrogen fixation

FIG. 24.17 Diversity of form among cyanobacteria.

In contrast to the monophyly of cyanobacteria, molecular sequence comparisons show that *anoxygenic* photosynthesis is distributed widely on the bacterial tree (see [Fig. 24.16](#)). Think of the purple layer beneath the surface of many microbial mats (see [Fig. 24.7](#)). The vivid color comes from the light-sensitive pigments of the aptly named purple bacteria, found within the Proteobacteria. Purple bacteria are capable of

photoautotrophic growth using bacteriochlorophyll and a single photosystem. Most show evidence of metabolic versatility: when light or appropriate electron donors are absent, they can grow as heterotrophs.

A green layer lies beneath the surface of other microbial mats, its color caused by light reflected by the pigments of another group of photosynthetic bacteria, called green sulfur bacteria because they commonly gain electrons from hydrogen sulfide and deposit elemental sulfur on their walls. Unlike most groups of photosynthetic bacteria, the green sulfur bacteria are intolerant of oxygen gas. Oddly, a species of green sulfur bacteria has been found in hydrothermal rift vents 2 km beneath the surface of the ocean. Light doesn't penetrate to these depths, so if these organisms harvest light, it must come from incandescent lava as it erupts on the bottom of the ocean.

Light-harvesting bacteria occur on several other branches of the bacterial tree—the photoheterotrophic heliobacteria, for example, and the green nonsulfur bacteria often found in freshwater hot springs. Despite a century of research, our knowledge of photosynthesis within the bacterial tree remains incomplete, as illustrated by the discovery in 2007 of unique light-harvesting bacteria in Yellowstone National Park. Genomic surveys of hot springs turned up evidence of a previously unknown microorganism containing bacteriochlorophyll, and gene sequencing established that this organism belongs to the phylum Acidobacteria. There is no evidence for carbon fixation, however, and recent success in culturing this Yellowstone bacterium confirms that it is a photoheterotroph.

Self-Assessment Question

10. Name and describe three major groups of Bacteria.

## 24.5 ARCHAEAL DIVERSITY

We have already noted that Archaea and Bacteria are prokaryotic, but differ in their membrane and wall composition, molecular mechanisms for transcription and translation, and many other biological features (see [Table 24.1](#)). As a result, the two groups tend to thrive in very different environments. Many archaeons tolerate environmental extremes such as heat and acidity. In fact, for many environmental conditions, archaeons define the known limits of life. Do these disparate environments have anything in common that might help us to understand the biology of Archaea? One proposal is that archaeons thrive in environments where the energy available to fuel cell activities is limited—where there is no light, or a limited abundance of fuels and oxidants for chemoautotrophy or respiration, or both. That is, archaeons commonly live where energy resources are too low to support bacteria and eukaryotes.

Bacteria and Archaea diverged from their last common ancestor more than 3 billion years ago. Just as with the Bacteria, the diversity of Archaea defies easy categorization. Archaea include many distinct types of organisms, and new groups are being discovered every year. In turn, as new archaeons are discovered, the shape of the archaeal tree changes. [Fig. 24.18](#) shows a recent phylogeny, in which the three main groups are labeled Euryarchaeota, TACK, and DPANN. The names of the latter two are based on the initials of major subgroups that make up these branches. Remarkably, the diverse DPANN group has come to light only over the past few years. Like the Bacteria, the Archaea include forms able to respire aerobically or anaerobically, as well as

chemoautotrophs and fermenters. There are, however, metabolic differences between the two domains. No Archaea carry out photosynthesis using chlorophyll and related pigments, but some Archaea exhibit forms of energy metabolism unknown in bacteria or eukaryotes.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

FIG. 24.18 Phylogeny of Archaea. Different branches of the domain have evolved distinct temperature preferences, salt tolerance, acid tolerance, and production of methane. Data from Williams, T. A. et al., 2017, "Integrative Modeling of Gene and Genome Evolution Roots the Archaeal Tree of Life," *Proceedings of the National Academy of Sciences USA* 114:E4602–E4611.

The archaeal tree has anaerobic,

## hyperthermophilic organisms near its base.

Archaeons that branch from lower nodes of the archaeal tree exhibit a remarkable ability to grow and reproduce at temperatures of 80°C or more. Called [hyperthermophiles](#), these organisms do not simply tolerate high temperatures; they require them for survival. At present, the world record for high-temperature growth is held by *Methanopyrus kandleri*, an archaeon that grows at 122°C among hydrothermal vents on the seafloor beneath the Gulf of California. Most of these heat-loving archaeons are anaerobic. They live as anaerobic respirers or as chemoautotrophs that obtain energy from the oxidation of hydrogen gas.

Why do anaerobic hyperthermophiles sit on the lowest branches of the archaeal tree? Many biologists believe that Archaea first evolved in hot environments with no oxygen. As we discussed in [Chapter 22](#), geologists agree that oxygen gas was not present on the early Earth, consistent with the inference we can make from the archaeal tree that early Archaea were anaerobic. A hot environment for early Archaea can be understood in two ways. Either the entire ocean was hot—for which there is little evidence—or Archaea first evolved in hot springs where they could live as chemoautotrophs deriving energy from local supplies of hydrogen and metals. Because some versions of the bacterial tree also show hyperthermophilic species branching from the earliest nodes, it has been suggested that the last common ancestor of *all* living organisms lived in a hot, oxygen-free environment.

## The Archaea include several groups of acid-loving microorganisms.

In many parts of the globe where humans mine coal or metal ores, abandoned mines fill up with very acidic water. Called acid mine drainage, this water has been acidified through the oxidation of pyrite ( $\text{FeS}_2$ ) and other sulfide minerals to produce sulfuric acid ( $\text{H}_2\text{SO}_4$ ). The pH of these waters is commonly in the range of 1 to 2, and can actually fall to near 0. To us, acid mine drainage is an environmental catastrophe, but a number of archaeons thrive in it ([Fig. 24.19](#)). Their modified protein and membrane structures enable them to tolerate these harsh conditions, making it possible to use sulfur compounds in the environment for both chemoautotrophic and heterotrophic growth. What is the limit to growth at low pH? *Picrophilus torridus*, a euryarchaeote archaeon, grows optimally at 60°C and in environments with a pH of 0.7—the pH of battery acid. It is capable of growth in environments down to pH 0, which is a record, as far as we know. In fact, *P. torridus* requires an acidic environment. It will not grow in rainwater because the pH is too high.

Source: Andrew Knoll, Harvard University.

FIG. 24.19 Headwaters of the Rio Tinto, southwestern Spain. Archaeons thrive in these highly acidic waters, pH 1–2.

## Only Archaea produce methane as a by-product of energy metabolism.

Euryarchaeotes include Earth's only biological source of natural gas, or methane ( $\text{CH}_4$ ). Known as **methanogens**, they generate methane by fermenting acetate ( $\text{CH}_3\text{COO}^-$ ) or by chemoautotrophic pathways in which hydrogen gas ( $\text{H}_2$ ) reduces  $\text{CO}_2$  to  $\text{CH}_4$ . Methanogenic Archaea play an important role in the carbon cycle, recycling organic molecules in environments where the supplies of electron acceptors for respiration are limited.

Most methanogens live in soil or sediments. They are particularly prominent in peats and lake bottoms where sulfate levels are low and bacterial sulfate reduction is limited. Some, however, live in the rumens (a specialized chamber in the gut) of cows ([Case 5](#)), helping to maximize the energy yield from ingested grass. Methane doesn't last long in the atmosphere; it is quickly oxidized to carbon dioxide. Nonetheless, the steady supply of methane generated by archaeons makes a significant contribution to the greenhouse properties of the atmosphere. For this reason, biologists are interested in how methanogenic Archaea will respond to twenty-first-century climate change ([Chapter 48](#)).

## One group of the Euryarchaeota thrives in extremely salty environments.

Methanogens are not the only unique euryarchaeotes. A related group illustrates the limits of tolerance to another environmental condition—salinity, or saltiness. The Haloarchaea are halophilic (salt-loving) photoheterotrophs that use the protein bacteriorhodopsin to absorb energy from sunlight (see [Fig. 24.6](#)). They live in waters that are salty enough to precipitate table salt (NaCl), maintaining osmotic balance by accumulating ions (especially  $K^+$ ) and organic solutes in their cytoplasm. Just as extreme acidophiles require acid conditions, these extreme halophiles require high salt conditions and cannot live in dilute water.

## Thaumarchaeota may be the most

## abundant cells in the deep ocean.

Environmental sequencing has yielded another surprise discovery: the immense volumes of water beneath the surface waters of the oceans contain vast numbers of archaeons. In the deep ocean, these organisms may be nearly as abundant as the total number of bacteria in the oceans. Recently segregated as the Thaumarchaeota (the T in TACK), these archaeons are chemoautotrophs that derive energy from the oxidation of ammonia ([Fig. 24.20](#)). It is becoming clear that Thaumarchaeota play an important, if only recently recognized, role in the marine nitrogen cycle.

### HOW DO WE KNOW?

## FIG. 24.20

### How abundant are archaeons in the oceans?

#### BACKGROUND

Early exploration of microbial diversity in the oceans revealed that archaeons are tremendously abundant. Just how abundant are they, and which metabolisms do they employ to obtain energy and carbon?

#### METHOD

Marine biologists sampled seawater throughout the depth of the ocean at a test site in the northern Pacific Ocean. To the samples, they added molecular tags bound to fluorescent molecules that are visible under the microscope. The tags were RNA sequences that bind to small-subunit ribosomal RNA genes known to be useful in identifying different types of bacteria and archaeons. In this way, separate and distinct fluorescent markers were attached to thaumarchaeote archaeons (a group within the TACK Archaea), euryarchaeote archaeons, and bacteria.

#### RESULTS

By counting the cells marked by different fluorescent tags in seawater samples, the biologists showed that most cells near the surface are bacteria, but thaumarchaeotes make up approximately 40% of all cells in deeper waters ([Fig. 24.20a](#)).

## CONCLUSION

Marine Thaumarchaeota, unknown in 1990, are now known to be among the most abundant organisms in the oceans.

## FOLLOW-UP WORK

Archaea are among the most abundant of all cells in the world's oceans. How do these cells live? Biologists have taken microbial samples from water known to be sites of nitrification (that is, the conversion of ammonia to nitrite or nitrate). These samples contained an abundance of thaumarchaeote cells, supporting the hypothesis that thaumarchaeotes are nitrifiers. In fact, the higher the abundance of thaumarchaeote cells ([Fig.](#)

[24.20b](#), dark blue line), the higher the amount of nitrite produced ([Fig. 24.20b](#), light blue line). Thaumarchaeotes grown in culture were shown to grow by consuming ammonia ([Fig. 24.20b](#), red line). In other words, these organisms oxidize ammonia to provide the ATP and reducing power needed to incorporate CO<sub>2</sub> into organic molecules. In doing so, they play a major role in the marine nitrogen cycle, thriving where sources of carbon and energy for other types of metabolism are scarce.

SOURCES Karner, M. B., E. F. DeLong, and D. M. Karl. 2001. "Archaeal Dominance in the Mesopelagic Zone of the Pacific Ocean." *Nature* 409:507–510 (The figure has been modified to reflect more recent nomenclature.); Könneke, K., et al. 2005. "Isolation of an Autotrophic Ammonia-Oxidizing Marine Archaeon." *Nature* 437:543–546.

Like the discovery of SAR11, the discovery of marine thaumarchaeotes makes it clear that before the still-emerging age of environmental genetics and genomics, we simply didn't have a very good idea of which microorganisms lived where and did what in the oceans. Fortunately, that situation is changing rapidly.

### Self-Assessment Questions

11. What are three environmental extremes where Archaea thrive?
12. If early branches on the bacterial and archaeal trees are dominated by hyperthermophilic microorganisms, does this mean that the early oceans were very hot?

## 24.6 THE EVOLUTIONARY HISTORY OF PROKARYOTES

On the tree of life, the plants and animals of our familiar existence populate only the most recent branches. For most of Earth's history, life was entirely microbial. Perhaps surprisingly given their small size, Bacteria and Archaea have left a fossil record that allows paleontologists to reconstruct aspects of life's early evolution.

Sedimentary rocks preserve microscopic fossils of ancient bacteria, including the photosynthetic cyanobacteria ([Fig. 24.21](#)). Limestones and related rocks also preserve [stromatolites](#), layered structures that record sediment accumulation by microbial communities ([Fig. 24.22](#)). Some especially well-preserved ancient rocks also contain molecular fossils—biomolecules, usually lipids, that resist decay and so preserve a chemical signature of ancient life.

Source: a–c. Andrew Knoll, Harvard University.

FIG. 24.21 Bacterial microfossils. (a) Bacteria that probably metabolized iron in 1.9-billion-year-old rock from the Gunflint Formation in northwest Ontario, Canada. (b) Cyanobacteria preserved in 800-million-year-old silicified marine carbonates from the Draken Formation in Spitsbergen, Norway. (c) A short cyanobacterial filament from silicified tidal flat carbonates of the 1.5-billion-year-

old Bilyakh Group in northern Siberia.

Sources: (top) Andrew Knoll, Harvard University; (bottom) François Gohier/Science Source.

**FIG. 24.22 Stromatolites.** Modern-day stromatolites at Shark Bay, Western Australia (top), show microbial communities building the domed structures exhibited by stromatolites in ancient rocks (bottom). Stromatolites are among the earliest records of life on Earth.

Life originated early in our planet's history.

The Earth is approximately 4.6 billion years old, but few sedimentary rocks have survived destruction by geologic processes and remain to document our planet's earliest history. Sedimentary rocks deposited nearly 3.5 billion years ago in Western Australia and South Africa provide some of our earliest records of Earth's history. Remarkably, they contain a scarce but discernible signature of life. Tiny organic structures preserved in these rocks have been interpreted as microfossils, although this conclusion remains controversial.

More pervasive (and persuasive) evidence of life in early oceans is provided by stromatolites. Stromatolites in ancient rocks are strikingly similar to modern structures formed by microbial communities and so provide evidence of life that goes back about 3.5 billion years ([Fig. 24.22](#)). Also, because purely physical processes cannot explain the isotopic composition of carbon in very old limestones and organic matter, we can conclude that a biological carbon cycle existed 3.5 billion years ago (and, from the evidence of 3.8-billion-year-old rocks in Greenland, possibly earlier).

The chemistry of Earth's oldest sedimentary rocks also shows that the early atmosphere and ocean contained little or no free oxygen. What would the carbon cycle look like on an oxygen-free planet? We know the answer from our discussion of prokaryotic metabolism. Photosynthesis can incorporate  $\text{CO}_2$  into organic molecules in oxygen-poor waters, using  $\text{H}_2\text{S}$ ,  $\text{H}_2$ , or  $\text{Fe}^{2+}$  as electron donors, and fermenters and anaerobic respirers can recycle carbon, releasing  $\text{CO}_2$  back into the environment, using electron acceptors such as  $\text{SO}_4^{2-}$  and  $\text{Fe}^{3+}$ . Geologic evidence suggests that iron played a particularly important

role in cycling carbon for the first billion years of evolutionary history.

The evolution of cyanobacteria, with their capacity for oxygenic photosynthesis, made possible the accumulation of oxygen in the atmosphere and oceans. Oxygen began to accumulate in the atmosphere approximately 2.4 billion years ago, making possible aerobic respiration and, eventually, our present-day carbon cycle. Both microfossils and molecular fossils indicate that cyanobacteria and other photosynthetic bacteria continued to dominate primary production until about 650 million years ago. Thus, our modern carbon cycle, powered overwhelmingly by oxygenic photosynthesis and with major participation by eukaryotic organisms, may have existed for only the last 15% of Earth's history.

## Prokaryotes have coevolved with eukaryotes.

Even after the rise of eukaryotic cells and, later, plants and animals, Bacteria and Archaea have remained essential to the functioning of biogeochemical cycles and hence to the maintenance of habitable environments on Earth. Prokaryotic organisms have also radiated into the many novel environments made possible by eukaryotes. We noted earlier that bacteria fix nitrogen in nodules formed on soybean roots. Soybeans and nitrogen-fixing bacteria have evolved together, in a process called [coevolution](#).

Coevolutionary relationships between prokaryotic microorganisms and eukaryotes are common in nature. As noted earlier, cows metabolize grass with the help of methanogenic archaeons in the

rumen, a specialized digestive organ. These microbes enable the cow to gain nutrition from plant materials that could otherwise not be digested; in turn, the microorganisms benefit from a steady supply of food. Similarly, clams that live near methane-rich vents in the Gulf of Mexico have evolved specialized organs that house methane-oxidizing bacteria. These chemoautotrophic bacteria excrete organic compounds that provide the clams with a reliable source of nutrition.

Bacteria can affect animal behavior as well as nutrition. For example, some squid species attract mates by emitting light from specialized organs full of bioluminescent bacteria ([Case 5](#)). The bacteria provide the squid with a mechanism for communication in the dark deep-sea environment, and the squid feeds the bacteria. Interestingly, many different kinds of bacteria live in the waters that surround the squid, but only the bioluminescent species accumulates in the squid's light organ. Molecular signals enable the squid and bacteria to recognize and respond to each other.

Bacteria can also influence animal reproduction. Earth supports more than 1 million species of insects, and perhaps two-thirds of these harbor the proteobacterial parasite *Wolbachia* within their tissues. A heterotroph that obtains nutrition by metabolizing organic compounds supplied by its host, *Wolbachia* infects its host's reproductive tissues and passes from one generation to the next in the host's eggs ([Fig. 24.23](#)). Remarkably, many *Wolbachia* strains alter the host's reproductive cells so that the insect host can successfully reproduce only with partners infected by the same *Wolbachia* strain. Because *Wolbachia* is transferred by eggs and not sperm, these organisms have

little use for males. Consequently, some cause male host embryos to die, increasing the proportion of females. Others cause genetically male embryos to develop as females, or enable eggs to develop into female embryos without fertilization.

Source: Image by Zoe Veneti and Kostas Bourtzis.

FIG. 24.23 A large population of *Wolbachia* bacteria (fluorescing green) in the embryo of a fruit fly. *Wolbachia* can influence the development and reproductive biology of their animal hosts.

*Wolbachia* has another effect on its insect hosts that is highly relevant to human health: it commonly inhibits infection by viruses and the eukaryotic parasites that cause malaria. Recent research shows that *Wolbachia* populations in some fly species protect their hosts against infection by RNA viruses. Scientists introduced these bacteria into mosquitos that transmit dengue fever, a tropical disease that infects 50–100 million people each year. The *Wolbachia*-infected mosquitos were strongly resistant to the dengue virus, which causes dengue fever. Moreover, when introduced into the wild, these virus-resistant forms

rapidly expand to dominate regional mosquito populations. *Wolbachia* parasites present a possible path to controlling dengue fever, malaria, and other insect-borne diseases.

All around us, plants, animals, and microorganisms live in intimate association—sometimes to our detriment, but often in mutually beneficial relationships that influence how we grow, develop, eat, and behave. Humans are no exception.

## CASE 5 THE HUMAN MICROBIOME: DIVERSITY WITHIN

### How do intestinal bacteria influence human health?

It has been estimated that the bacteria (and, to a much lesser extent, archaeons) in and on your body match or outnumber your own cells. Estimates of the number of microbial species that inhabit our bodies vary, but approximately 750 types have been identified in the mouth alone, and the list remains incomplete ([Fig. 24.24](#)). A comparable diversity resides in the colon, and still more bacteria live on the skin and elsewhere. Some are transients, entering and leaving the body within a few bacterial generations. Others are specifically adapted for life within humans, forming complex communities of interacting species.

FIG. 24.24 The human microbiome. This chart provides a rough guide to the distribution of the 3000 or more species of bacteria found on and within a healthy human adult, showing the locations of bacteria that had been sequenced as of 2010. Data from J. Peterson et al., 2009, “The NIH Human Microbiome Project,” *Genome Research* 19:2317–2323; originally published online October 9, 2009.

At present, much research is focused on the bacteria within our intestinal tracts. We commonly think of gut bacteria as harmful, but this perception arises from only a small—albeit devastating—subset of our microbial guests. Illnesses known to be caused by bacteria within our bodies include cholera, dysentery, and tuberculosis. Once the leading causes of death in New York and London, these diseases remain major killers in Africa. Other diseases, not previously thought to be of microbial origin, are now known to be caused by bacteria—ulcers, for example, and stomach cancer, both mediated by the acid-tolerant bacterium *Helicobacter pylori*. More often than not, however, intestinal bacteria have a beneficial effect. They help to break down food in our digestive system and secrete vitamins and other

biomolecules into the colon for absorption into our tissues. Molecular signals from bacteria guide the proper development of cells that line the interior of our intestines.

A fertilized human egg has no bacteria attached to it, so our microscopic passengers arrive by colonization—by infection, if you will. Research on children from Europe and rural Africa clearly shows the importance of diet in establishing our gut microbiota ([Fig. 24.25](#)). African children, who are typically raised on a diet low in fat and animal protein but rich in plant matter, have gut microbiotas enriched in species of the phylum Bacteroidetes that are known to help digest cellulose. In contrast, European children, when raised on a typical Western diet rich in sugar and animal fat, lack these bacteria, harboring instead diverse members of the phylum Firmicutes. We do not understand the full ramifications of these differences, but active research suggests that they may help to explain the relative prominence in Western societies of allergies and other disorders involving the immune system.

Morris, *Biology: How Life Works*, 3e, © 2019 W. H. Freeman and Company

**FIG. 24.25 Diet and the intestinal microbiota.** Studies of gut bacteria in children from (a) rural Africa and (b) Western Europe show markedly different communities. Data from C. De Filippo, D. Cavalieri, M. Di Paola, M. Ramazzotti, J. B. Poullet, S. Massart, S. Collini, G. Pieraccini, and P. Lionetti, 2010, “Impact of Diet in Shaping Gut Microbiota Revealed by a Comparative Study in Children from Europe and Rural Africa,” *Proceedings of the National Academy of Sciences USA* 107(33):14693, doi:10.1073/pnas.1005963107.

We also influence our gut biota by ingesting antibiotics. Although prescribed for the control of pathogens, most antibiotics kill a wide range of bacteria and, therefore, can change the balance of our intestinal microbiota. Clinical studies show that the incidence of inflammatory bowel disease, a disabling inflammation of the colon, increases in humans who have been treated with antibiotics.

To understand the relationships between the human microbiome and human health, we need to know what constitutes a healthy gut biota. This means studying the metabolism, ecology, and population genetics of the bacteria in our bodies. We need to know which bacteria have evolved to take advantage of the environments provided by the human digestive system, and which are “just passing through.” Future visits to the doctor may include routine genetic fingerprinting of our bacterial biota, as well as treatments designed to keep our microbiome—and, so, ourselves—healthy.

#### Self-Assessment Question

13. What is the age of the Earth, and when is life thought to have first originated?

## CORE CONCEPTS SUMMARY

**24.1 TWO PROKARYOTIC DOMAINS:** The two prokaryotic domains are Bacteria and Archaea.

Prokaryotic cells are cells that lack a nucleus; they include Bacteria and Archaea. [page 519](#)

Bacteria are small and lack membrane-bounded organelles. [page 519](#)

The bacterial genome is circular. Some bacteria also carry smaller circles of DNA called plasmids. [page 520](#)

Diffusion limits size in bacterial cells. [page 520](#)

Bacteria can obtain DNA by horizontal gene transfer from organisms that may be distantly related. [page 522](#)

Like Bacteria, Archaea lack a nucleus, but they collectively form a second prokaryotic domain that is distinct from Bacteria. [page 523](#)

Some archaeons are extremophiles, living in environments characterized by low pH, high salinity, or high temperatures. Others live in less extreme environments such as the upper ocean or soil. [page 523](#)

**24.2 AN EXPANDED CARBON CYCLE:** Bacteria and Archaea cycle carbon in diverse ways.

Bacteria are capable of oxygenic photosynthesis, using water as a source of electrons and producing oxygen as a by-product, and of anoxygenic photosynthesis, using electron donors other than water,

such as  $\text{H}_2\text{S}$ ,  $\text{H}_2$ , and  $\text{Fe}^{2+}$ . [page 525](#)

Some bacteria and archaeons are capable of anaerobic respiration, in which  $\text{NO}_3^-$ ,  $\text{SO}_4^{2-}$ ,  $\text{Mn}^{4+}$ , and  $\text{Fe}^{3+}$  serve as the electron acceptor instead of oxygen gas. [page 526](#)

Many bacteria and archaeons obtain energy from fermentation, which involves the partial oxidation of organic molecules and the production of ATP in limited quantities. [page 527](#)

Some photosynthetic bacteria are photoheterotrophs, obtaining energy from sunlight but using preformed organic compounds rather than  $\text{CO}_2$  as a source of carbon. [page 527](#)

Chemoautotrophy, in which chemical energy is used to convert  $\text{CO}_2$  to organic molecules, is unique to Bacteria and Archaea. [page 527](#)

### **24.3 SULFUR AND NITROGEN CYCLES:** Bacteria and Archaea are critical to the biological cycling of sulfur and nitrogen.
